As already mentioned the pain of duodenal ulcer commences when the stomach is nearly empty, that is, usually about three hours after a meal. There is not general agreement as to the mechanism whereby the pain is produced. It is generally conceded, however, that it is not due to the direct stimulation of pain endings in the ulcer by acid or by food; pain fibers of the gastro-intestinal tract are not sensitive to chemical or the ordinary types of mechanical stimuli, tension is their adequate stimulus (p. 516). Nevertheless, that the acidity of the chyme is an important factor in the production of pain is evidenced by the experiments of Palmer and others. Palmer found that the introduction of 300 cc. or so of a 0.5 per cent solution of hydrochloric acid into the empty stomach of ulcer patients caused pain. This procedure

aroused no sensation in normal persons. The pain is therefore considered by most observers to be a consequence, though an indirect one, of the stimulation of afferent nerves in the base of the ulcer by the acid chyme. Disturbances of the motor mechanism of the stomach or duodenal cap (p. 484) dependent upon reflexes initiated from the irritable focus are believed to be the cause of the pain.

An observation of Dragstedt and Palmer suggests that in some instances the nerves of the ulcer, as a result of inflammation, may have become so hypersensitive that they give rise to pain in response to stimuli to which healthy visceral nerves are insensitive. It was found that gentle stroking of the surface of an ulcer, in a conscious patient during an operation, caused pain. Although spasm of the intestinal muscle occurred in the region of the ulcer, and this was painful, the ulcer surface itself appeared to be directly sensitive to mechanical and chemical stimulation. Irrigating it with acid was followed by pain which was relieved by the application of sodium bicarbonate.

Although motor disturbances of the pyloric and duodenal region are probably, in most instances, responsible for the ulcer pain, there is not general agreement as to their precise nature. According to some, spasm of the pylorus (pylorospasm), is responsible. Hurst considers that *achalasia* of the sphincter, i.e., a failure to relax upon the approach of a peristaltic wave (p. 516) rather than actual spasm exists. The immediate cause of the pain he believes to be the distention of the wall of the pyloric antrum as a powerful peristaltic wave drives fluid downwards against a pylorus which fails to open. The observations that pain may occur in the absence of peristaltic activity in the stomach, and be absent during gastric hypermotility, and that the pain is often continuous rather than intermittent, are opposed to this conception. Ryle attributes the pain to a general increase of gastric tone. The researches of Wilson indicate that the pain of duodenal ulcer is due to contraction of the duodenal cap. He examined the stomach of patients with duodenal ulcer under the fluoroscope after the ingestion of a barium meal, and during the pain. By moderate pressure upon the stomach through the abdominal wall he was able to drive fluid through the pylorus. In 14 out of 16 subjects the entrance of fluid into the duodenal cap was followed by relaxation (receptive relaxation) of the latter and the relief of pain. The ease with which material

was pressed into the cap argues against the existence of a degree of pylorospasm, or achalasia which could result in painful distention of the antrum. Furthermore, in many instances pain was experienced though the stomach was free from peristalsis. In view of these observations associating contractions of the wall of the duodenal cap with ulcer pain, it is quite conceivable that such contractions by causing tension (the adequate stimulus for gastro-intestinal pain) to be exerted upon inflamed nerve endings in the base of the ulcer are responsible for the sensation.

On the other hand, if the pain originates in this way how are we to account for the immediate relief which frequently follows the ingestion of food or of sodium bicarbonate? The relief, in some instances, occurs too rapidly to be accounted for simply by a reduction in acidity of the gastric contents. Are we to assume that in the case of bicarbonate ingestion the gas evolved passes at once through the pylorus and causes relaxation of the walls of the duodenal cap in the same manner as does fluid material forced through the pylorus by manual pressure? On the other hand, does the ingested food, or the evolved gas, by increasing the volume of the gastric contents abolish the pain by causing an adaptive relaxation of the gastric walls (p. 484). This is Ryle's suggestion. Definite answers to these questions are not forthcoming and the immediate cause of the pain of duodenal ulcer is still under debate.

Pain, in some instances, is due, apparently, to the spread of the inflammatory process to the serous coat and the traction of peritoneal adhesions. Pain of this nature is influenced by posture, disappearing usually when the subject reclines.

The application of physiological principles to treatment

The modern medical treatment of duodenal ulcer comprises the following measures. (a) Meals at frequent intervals; this practice has the two-fold effect of reducing gastric acidity and furnishing digestive products (probably peptones) which, as shown by the experiments of Mann and Bollman, exert a protective action against the action of acid. (b) The inclusion in the diet of such materials as cream and milk which, by inhibiting gastric secretion, causing the expulsion of bile from the gall-bladder and stimulating the

secretion of pancreatic juice, tend to reduce the acidity of the duodenal contents. (c) The limitation of highly seasoned foods and materials rich in extractives, especially meats and alcohol, which stimulate the gastric glands. (d) The omission from the diet of coarse indigestible articles, e.g., raw fruits and vegetables, which are likely to cause mechanical irritation of the ulcer. (e) The administration of alkalis, such as sodium bicarbonate to neutralize the acid, or of mucin which has a high acid-combining power (p. 427), and serves to form a protective coating for the ulcer. Entero-gastrone (p. 436) has recently been advocated as a means of inhibiting gastric secretion and motility. There is real danger of inducing alkalosis by the prolonged administration of readily absorbable alkaline salts such as sodium bicarbonate. Tri-calcium phosphate, calcium carbonate and magnesium oxide, and colloidal aluminum hydroxide although less efficient antacids are much less likely to induce alkalosis owing to their relatively slight absorption. The last mentioned chemical also inhibits secretion and inactivates pepsin. (f) Atropine is sometimes employed to reduce secretion. (g) The avoidance of overwork, mental or physical fatigue, worry or any psychic state likely to bring the neurogenic factor into play (p. 446).

In the treatment of duodenal ulcer, surgery is resorted to much less frequently today than in the past. When some complicating feature, (e.g., hemorrhage, perforation or pyloric obstruction) calls for operative treatment, one or other of the following procedures is usually undertaken with the object of effecting a radical cure. (a) Excision of the ulcer and reconstruction of the duodeno-pyloric region (pyloroplasty). (b) Anastomosis of the jejunum to the posterior aspect of the stomach at the lower part of the greater curvature (posterior gastroenterostomy). (c) A combination of (a) and (b). (d) Resection of the pyloric region of the stomach and of the ulcer-bearing area, and then either (i) anastomosing the cut end of the duodenum directly to the gastric stump (Billroth I type of operation), (ii) closing the duodenum and the gastric stump and performing a posterior gastrojejunostomy (Billroth II operation) or (iii) closing the duodenum and joining the jejunum to the gastric stump (Polya-Balfour operation).

CHAPTER XLI

DIGESTION IN THE INTESTINE

THE PANCREAS

STRUCTURE. (The pancreas is a racemose gland, its alveoli resembling those of the salivary gland in their general arrangement and design. Lying between the alveoli are groups of cells constituting the Islands of Langerhans which furnish the internal secretion of the pancreas (insulin, p. 577). The cells which line the alveoli and furnish the ferments of the pancreatic juice, contain, like the serous cells of the salivary glands and the chief cells of gastric tubules, zymogen granules which become reduced in number during secretory activity but re-accumulate after a period of rest. Two distinct zones may be seen in these cells, an inner lying next the alveolar lumen and containing the zymogen granules, and an outer which is clear and homogeneous. During secretion the outer clear zone increases in area at the expense of the granular zone.

The secretion is collected by a branching system of ducts which eventually lead into the main pancreatic duct—*duct of Wirsung*. This discharges in company with the common bile duct into the ampulla of Vater, which opens through a small orifice, situated upon the summit of a small papilla about $3\frac{1}{2}$ inches below the pylorus. In a certain proportion of cases the pancreatic and common bile ducts open into the intestine by separate orifices. An accessory pancreatic duct—*duct of Santorini*—is usually present. It opens into the duodenum about $\frac{3}{4}$ inch above the duct of Wirsung; it also sends a branch to the latter through which it delivered the greater part of its contents.

THE COMPOSITION OF PANCREATIC JUICE

The composition of pancreatic juice is given in table 33 modified from Starling. Its pH is between 7.10 and 8.20 (in dog).

The ferments of pancreatic juice are *trypsin*, *chymotrypsin*, *amylase*, *lipase*, *rennin* and *maltase*. Unlike the gastric enzymes, apparently those of pancreatic juice are produced by one type of cell.

Pancreatic proteinases

There are at least two proteinases in pancreatic juice—*trypsin* and *chymotrypsin*. A third, *heterotrypsin* has been described. Trypsin is not secreted as such but in an inactive form called *trypsinogen*. The activation was first shown by Schepowalnikow in Pavlov's laboratory to be brought about by the addition of a small quantity of intestinal juice or extract of the intestinal mucosa. The activation is due to an enzyme

called *enterokinase*. It has been denied by some (e.g. Waldschmidt-Leitz) that enterokinase is a true enzyme, but, as a result of the work of Kunitz, its enzymic nature is now accepted. Pure trypsinogen is also activated by allowing it to stand in a neutral solution, by the addition of trypsin, of magnesium or ammonium sulphate, or by allowing the pancreas to lie in a slightly acid solution before extraction. Calcium salts also have the power to activate trypsin. Chymotrypsin is also secreted in an inactive form, *chymotrypsinogen* and is activated by enterokinase but not by trypsin. These two enzymes, trypsin and chymotrypsin, are mainly responsible for the proteolytic activity of pancreatic juice. Both enzymes are proteins and they, as well as their precursors, have been obtained in pure crystalline form. Trypsin has no milk-curdling power, but is capable of clotting blood, whereas chymotrypsin, although it will not cause coagulation of blood has a powerful milk-curdling action, and is probably identical with pancreatic rennin. The optimum pH for the action of trypsin and of chymotrypsin is around 8; that of enterokinase is within the range between pH 5.2 to pH 6.0.

The *action* of trypsin carries the digestion of protein beyond the peptone stage. It also differs from peptic digestion in being carried on in an alkaline instead of in an acid medium. It is possible, moreover, that different linkages in the protein molecule are attacked by the two enzymes. Though under ordinary circumstances trypsin is called upon to commence its action after the gastric juice has converted a large part of the protein into proteoses and peptones, it can also attack native protein; flesh introduced directly into the duodenum is readily digested by the pancreatic juice. Nevertheless, the preparatory digestion of protein by gastric juice is favorable to tryptic action. The specific action of trypsin is to break the proteose and peptone fragments of the protein molecule into smaller amino-acid groups. These are generally termed *peptids*. In the earlier stages of tryptic digestion the amino groups are for the most part still relatively large—*poly-peptids*. Some of these are later split into groups containing 2, 3 or 4 amino-acids, constituting the *di-peptids*, *tri-peptids* and *tetra-peptids*; even a few

individual amino-acids, such as tyrosine and tryptophane are released. The complete breakdown of protein is reserved for the erepsin of the succus entericus (p. 455). The pancreatic juice itself also contains a small amount of erepsin.

Pancreatic amylase (amylopsin or diastase)

This has an action similar to but much more powerful than that of salivary amylase (ptyalin, see p. 421). In the hydrolysis of starch by pancreatic juice the same stages are passed through as have already been described for salivary digestion but they are completed in a fraction of the time, most of the starch being converted into maltose within a few minutes. Due to traces of *maltase* small amounts of glucose are also formed in the final stages of the pancreatic digestion of starch. Pancreatic amylase unlike the corresponding salivary enzyme is capable of digesting unboiled

TABLE 33

starch. Raw corn and wheat starch may be converted entirely into maltose, and raw potato starch is transformed to the extent of 80 per cent. It is important to remember in connection with infant feeding that during the first few weeks of life pancreatic amylase, the only really efficient ferment for the digestion of starches, is absent from the pancreatic juice. Little provision has been made for the digestion at this time of any other food than the natural one—milk.

The amylolytic ferment of the pancreas acts in a neutral, slightly alkaline or slightly acid medium. It acts to best advantage when the medium is faintly acid or neutral in reaction, its pH optimum ranging from 6.7 to 7.0. Certain inorganic ions, especially Cl, are absolutely essential for its action; if these be separated from pancreatic juice by dialysis the juice is deprived of its starch-splitting power. Part of the diastase is believed

to be re-absorbed from the intestine and excreted in the urine (p. 451).

Pancreatic lipase or steapsin

Fat is not digested to any important extent until it has reached the intestine. Here the lipase splits the fat molecule into its constituents, fatty acid and glycerine (see p. 593). A certain proportion of the fatty acids combine with the alkali in the intestinal fluids to form soaps. These through their property of lowering surface tension aid the division of the fat into smaller globules; a finer emulsion of fat with the intestinal juices results and the total surface area of the fat exposed to enzyme action is thereby increased.¹ The bile salts (p. 457) have a similar but more important effect upon the emulsification process. They therefore greatly enhance the fat-splitting action of steapsin. The reactions are shown in the following equations.

Pancreatic rennin has an action similar to that of gastric rennin (p. 427), but the pancreatic juice has a much more powerful milk-curdling power than has gastric juice. It is probable that the action is not due to a separate enzyme but to chymotrypsin (p. 449).

Disorders of the digestive function of the pancreas

In chronic pancreatic disease (chronic pancreatitis) the digestive power of the juice secreted by the gland becomes markedly reduced with the result that the feces contain quantities of undigested fat, protein and starch. The stools are increased in bulk and pale, and there may be diarrhea (pancreatogenous diarrhea). Several clinical tests have been devised in order to determine the extent of the impairment of the digestive functions of the gland. The microscopical examination of the feces for intact muscle fibers after a meal of

¹ Soaps are not formed in an acid medium; any which have been formed in the alkaline juices become precipitated again as the acidity of the intestinal contents increases.

meat, or the estimation of the fecal fat often gives valuable information. Others estimate the enzyme activity of the duodenal contents withdrawn through a duodenal tube. *Acute pancreatitis* is associated with severe abdominal pain, vomiting and symptoms of shock. In the more severe types of the acute disease hemorrhages into the glandular substances with necrosis occur. Fat necrosis in the mesentery, omentum and peritoneum, as well as in the pancreas itself is commonly observed. This is caused by the escape of lipase from the disorganized gland.

Hemorrhagic pancreatitis has been thought to be the result of the obstruction of the outlet of the ampulla of Vater (gallstone, spasm of sphincter of Oddi or swelling of duodenal mucosa) and the passage, in consequence, of bile into the pancreatic duct system (Archibald). However, according to Dragstedt and his associates only about 60 per cent of cases of hemorrhagic pancreatitis arise in subjects of chronic biliary tract disease and in only about 10 per cent of these is the ampulla obstructed by a gallstone. Rich and Duff find that the reflux of bile into the pancreatic ducts is a rather infrequent accompaniment of hemorrhagic pancreatitis. When reflux of bile is observed obstruction of the pancreatic duct system with subsequent rupture of the duct wall and the escape of pancreatic juice into the interstitial tissue of the pancreas is believed by these observers to be the essential factor in the production of the hemorrhagic lesion, rather than the action of the bile itself. Obstruction to the flow of pancreatic juice, due to metaplasia of the epithelial lining of a branch of the pancreatic duct within the gland, is considered by Rich and Duff to be the commonest cause of acute pancreatitis. The ductules and acini behind the obstruction become dilated; rupture of the distended walls and the escape of digestive enzymes into the glandular substance is looked upon as the immediate cause of the disease. The interstitial tissue of the pancreas, in common with other tissues of the body, possesses the power to activate the trypsinogen of the pancreatic juice; digestion and necrosis of the blood vessels result. These observers found metaplasia of the duct epithelium and acinar dilatation in 13 of 24 cases of hemorrhagic pancreatitis. In most cases of the disease a gallstone was not found in the ampulla of Vater and the main pancreatic duct was unobstructed. It is pointed out that rupture of a dilated ductule or acinus is most likely to occur when the secretion pressure of pancreatic juice is high, i.e., after a large meal or the ingestion of alcohol.

A determination of the concentration of the amylase or lipase of the serum or of the output of amylase in the urine is valuable as a means of recognizing acute pancreatic disease. In pancreatic damage the urinary amylase and the concentration of amylase in the serum are greatly increased. A corresponding rise occurs in the serum lipase. The *secretin test* is of great value in investigation of pancreatic insufficiency, especially in chronic disease e.g. cystic fibrosis of the pancreas. In

performing the test a purified preparation of secretin is injected intravenously and the duodenal secretions withdrawn by suction through a duodenal tube. The secretions are collected in 20 minute periods for an hour following the injection and the enzyme activity (trypsin, lipase, amylase, and phosphatase) determined.

THE EFFECTS OF THE TOTAL DRAINAGE OF PANCREATIC JUICE TO THE EXTERIOR. Elman and McCaughan have demonstrated the fatal effect of the loss from the body of all the pancreatic juice. In dogs the survival time following the establishment of a pancreatic fistula through which the juice was drained to the exterior was from seven to eight days. Loss of electrolytes with consequent dehydration (p. 18) is undoubtedly a factor leading to this result, for the life of the animals can be prolonged by the intravenous administration of Ringer's solution. Death cannot, however, be prevented by this treatment, the animals succumbing in spite of it after some weeks. Nor do the animals die simply as a result of inanition, for it has been shown that in the absence from the intestine of the pancreatic juice as a result either of a pancreatic fistula or of pancreatectomy, sufficient quantities of food are digested and absorbed to maintain life for indefinite periods. It has been suggested, therefore, that the loss of some material essential to life other than salts and water is the cause of death.

Ligation of the pancreatic ducts in dogs is followed by defective digestion of all three types of food stuff. There is pronounced polyphagia, loss in weight and impairment of liver function (Ivy). The general nutrition of the animals is improved by feeding raw pancreas. No compensatory increase in the secretion of the enzymes of the succus entericus occurs.

THE REGULATION OF THE SECRETION OF PANCREATIC JUICE

The secretion of pancreatic juice is under both hormonal and nervous control.

The hormonal control

In 1902 Bayliss and Starling showed that an acid (HCl) extract of the duodenal mucosa when injected into the blood stream of an animal caused a copious flow of pancreatic juice. Intravenous injection of the acid itself was ineffective. A secretagogue effect also followed the introduction of acid into a loop of bowel whose nervous connections had been completely severed, the only communication between the bowel and the pancreas being then through the blood stream. The secretory effect was shown to be specific and not simply due to vasodilatation of the pancreatic vessels. The excitatory substance was called *secretin*.

The obvious physiological implication of these results was that the acid chyme upon coming into

contact with the duodenal mucosa caused the production, or liberation, of a substance which was then conveyed by the blood to the pancreatic cells. Ivy, Farrell and Lueth transplanted a loop of intestine and the tail of the pancreas to subcutaneous sites, thus isolating the two structures completely from extrinsic nervous control. They observed secretion from the pancreatic transplant when acid was placed in the isolated loop. Since the intravenous injection of acid alone is ineffective, this experiment affords conclusive evidence for the liberation of a hormone from the intestinal mucosa.² Mellanby and Huggett in 1926 demonstrated that secretin existed preformed in the mucosa from which it could be extracted by water, alcohol and other solvents as well as by acid. Bayliss and Starling had claimed that the hormone existed in an inactive or precursory form which they called *prosecretin*. Mellanby also showed that bile introduced into the duodenum caused secretin to be absorbed into the blood stream and that the active agent in the bile was the cholic acid of the bile salts. He suggested that the bile salts in their passage through the intestinal mucosa absorbed the secretin and carried it into the blood. Bile salts, however, though aiding in the absorption of the hormone are not absolutely essential. Ivy and his colleagues have shown that food (meat and fat) entering the intestine stimulates pancreatic secretion in the usual manner after ligation of the common bile duct.

The action of secretin is not reduced by atropine which paralyzes vagal endings or by ergotamine which paralyzes sympathetic secretory fibers; so there is no evidence that its production or absorption is influenced by nervous mechanisms, or that it stimulates parasympathetic or sympathetic terminals in the pancreas. It appears to be a direct excitant of the glandular cells. Secretin also stimulates the secretion of bile and probably of the succus entericus. Its chologogue effect is a direct one and not simply secondary to the liberation of metabolites from the activated pancreas.

Agren and associates have prepared secretin in pure crystalline form. It is a protein-like substance (molecular wt. 5000) giving a positive biuret but a negative ninhydrin reaction. It is basic in character, containing histidine and arginine but is free from cystine, tyrosine and tryptophane. This preparation and a cruder but non-toxic amorphous material have been used by these workers to test biliary and pan-

creatic functions in man. Ivy and Greengard have obtained secretin in the form of a crystalline picrolonate with the formula C_8H_5ON . The highest yield of secretin is given by the upper two-thirds of the small intestine. Minimal amounts are obtained from the lower third of the small intestine and from the ascending colon. It is absent from the gastric mucosa.

Pancreozymin. This is the name which Harper and Raper have given to a second pancreatic hormone obtained, like secretin, from extracts of duodenal mucosa. The existence of this hormone has been confirmed by Greengard and his associates. Unlike secretin it stimulates the secretion of trypsin, amylase and lipase.

The control of pancreatic secretion by nerves

It has been known since the important work of Pavlov on pancreatic secretion that the gland cells are excited by vagal impulses. Control of pancreatic secretion by the vagus was shown in the following way. The nerve was divided in the neck four days previously. This preliminary procedure has the effect of practically abolishing the irritability of the cardiac fibers since they degenerate before the secretory fibers. When the nerve prepared in this way is stimulated a well-marked secretion of juice occurs. The secretion is, however, much less pronounced than that which follows the injection of secretin. On this account it had been assumed that the secretion following nerve stimulation was of little importance. Mellanby has shown that this view is erroneous. The vagal secretion, though thick and scanty, is particularly rich in ferments. Indeed the secretion of ferments is mainly under vagal control. The chief effect of secretin, on the other hand, is to cause the secretion of the water and inorganic constituents, e.g., the bicarbonate of the pancreatic juice. Vagal stimulation causes exhaustion of the zymogen granules. Only after repeated injections of secretin do histological changes of a similar nature appear, and these are always less pronounced than those following nerve excitation. Apparently then, the extrusion of the colloidal zymogenous particles from the cells into the alveoli is largely controlled by nervous impulses. The hormone, on the other hand, causes a flow of alkaline fluid which serves to flush the alveoli, to thin the juice rich in organic materials and sweep it along the ducts. Pilocarpine acts similarly to vagal stimulation. Atropine annuls the nervous secretion but, as already mentioned, not that caused by secretin. Under certain circumstances a small secretion of pancreatic juice may be obtained by stimulation of the splanchnic nerve.

² The word, hormone, was used for the first time as a result of these experiments. They also furnished the first conclusive evidence of a hormonal mechanism.

This is probably a vascular effect. Pavlov showed that there is a psychic element in the control of pancreatic secretion. Though the effect is much less than in the case of gastric secretion, sham feeding was found very definitely to increase the pancreatic flow—a result which Ivy has confirmed.

THE ACTION OF THE CHYME UPON PANCREATIC SECRETION

Chyme escaping through the pylorus causes an approximately equivalent amount of alkaline fluid (bile and pancreatic juice) to enter the intestine. Among the substances in the chyme which exert the greatest secretagogue effect upon the pancreas are acids, meat extracts, protein derivatives, fats, fatty acids, soaps and water.

There is evidence that peptones, acids and soaps exert their action through local reflex mechanisms and that these in turn are influenced by vagal impulses. Crider and Thomas found that the effect of peptones and of acid (but not of soap) upon secretion was abolished immediately after section of the vagus nerves. Recovery occurred a few days later but the juice was reduced in volume and in its concentration of total nitrogen. They suggest that the vagus exerts its control upon the pancreatic secretion not directly but through augmentation or inhibition of the activity of the local reflexes.³ The splanchnic nerves, on the contrary, appear to be without effect upon pancreatic secretion initiated by chemical stimulation of the intestine. Peptone stimulation causes the secretion of a juice resembling that resulting from vagal stimulation, being of higher specific gravity and with a nitrogen concentration many times greater than that caused by acid, water or secretin. Peptone stimulation is also accompanied by depletion of the zymogen granules of the acinar cells (Ramsay, Thomas and Crider). It is possible that certain other products of digestion may enter the circulation and be carried directly to the gland (humoral mechanism, p. 434).

The adaptation of the concentrations of amylase and trypsin in the pancreatic juice and tissue to the predominant element of the diet

Grossman, Greengard and Ivy found that the amylase concentration in the pancreatic juice and tissue of rats maintained upon a diet predominantly carbohydrate was greatly increased and the trypsin content decreased. In animals on a high-protein diet,

³ It may be, as Greengard and his associates suggest, that the vagus exerts its effect simply through causing vasodilatation.

the trypsin content of the pancreas was increased and the amylase content reduced. A high fat diet had little effect, however, upon the production of pancreatic lipase or of trypsin but reduced the concentration of amylase in the pancreatic juice and tissue. The hydrolytic product of starch, namely, dextrose, increases the amylase content of the pancreas, but the products of protein(casein) have no such action upon trypsin production. Grossman and his associates suggest that amylase production is regulated through a humoral mechanism involving dextrose, whereas the tryptic content of the pancreas is controlled reflexly.

THE INTESTINAL JUICE

THE STRUCTURE OF THE INTESTINAL GLANDS

The intestinal juice or *succus entericus* is the name given to a specific secretion of innumerable glands scattered diffusely over the mucosa of the small intestine. The glands consist of minute tubular pits—the *crypts of Lieberkühn*—lined by cells which are continuous with the general epithelial covering of the mucosa. Glands of a similar character are present in the large intestine, including the appendix but their secretion possesses little or no digestive action. Confined to the duodenum, and especially numerous in its upper part, another type of gland is found; this is the gland of Brunner. The glands of Brunner resemble the gastric glands of the pyloric region and, like the latter, are tortuous and branching. Their secretion, also, like that of the pyloric glands, is alkaline; it contains mucus and a weak proteolytic ferment.

To the naked eye the mucosa of the small intestine presents a velvety appearance, due to the presence of immense numbers of minute slender processes which—like the pile of velvet—project from its surface. These are the *intestinal villi*. They are barely visible individually to the unaided sight and number from 20 to 40 to the square millimeter. They are absent from the large intestine. Each villus shows a lymph vessel (lacteal) which occupies its axis from the base to near its tip. An arteriole enters each villus, and from this a capillary plexus arises from which the blood is returned by one or two larger venules. The deeper regions of the pits formed between adjacent villi dip into the submucosa and constitute the intestinal glands or crypts of Lieberkühn (fig. 195). The cells covering the somewhat club-shaped extremities of the villi are columnar in shape, and peculiar in that their free borders show a very fine striation, the striae running perpendicular to the free surface of the cell. Many of the columnar cells become transformed into goblet cells and secrete mucus.

The cells lining the crypts of Lieberkühn are of four

types. (a) *Columnar cells*. (b) *Goblet cells*. These two types of cells are similar to those of the villi but do not possess the fine striations just referred to. The more superficial portion of the gland tubule is lined by these two cell types alone. (c) Large flask-shaped cells which stain with silver ammonium oxide. They are therefore known as *argentaffin cells* or *cells of Kultschitzsky*. These cells contain granules but their function is a disputed question. According to some they are endocrine elements, while others believe they supply ferments to the intestinal juice. (d) *Cells of Paneth*. These lie in the blind extremity of the glands of the ileum but not in those of the duodenum. Their

establishment of a *Thiry fistula*. This consists in completely isolating a loop of small bowel from the rest of the intestinal tract by two incisions placed from 6 to 10 inches apart, and then restoring the continuity of the bowel by an end to end anastomosis of the sections above and below the isolated portion. The blood vessels and nerves reaching the loop through its mesentery are left intact. One end of the loop may be closed by suture, the other end being left open and brought through the abdominal wound where it is fastened by sutures and the abdomen closed around it.

FIG. 195. Vertical section of the mucous membrane of the jejunum of adult man. The empty space, *a*, between the tunica propria and the epithelium of the villus is an artifact, the result of the shrinking action of the fixing fluid. The goblet cells have been drawn on one side of the villus on the right. (After Stöhr.)

protoplasm shows a fine reticulum and is studded with coarse granules. The function of these cells has not been definitely determined, but from their resemblance to the secretory cells of other digestive glands they are presumed to supply the ferments of the intestinal juice (fig. 196).

THE COMPOSITION OF THE INTESTINAL JUICE

Owing to the admixture of the succus entericus with the other intestinal secretions—pancreatic juice and bile—and to the fact that the glands are diffusely scattered throughout the mucosa, special means must be devised for its collection in the pure state. Pure juice may be obtained by the es-

It may be desirable to leave both ends open and stitch each into the abdominal wall a short distance apart. This constitutes a *Vella* (or *Thiry Vella*) fistula.

The *Mann-Bollman fistula*, so called after its inventors, is useful for certain types of investigation. A loop of ileum is isolated. The distal (aboral) end is anastomosed to the duodenum or any desired part of the small intestine; the proximal (oral) end is sutured to the abdominal wall. By giving the loop this direction in relation to the exterior, the peristaltic waves, which are inherently incapable of passing in any other than an aboral

direction along the bowel (p. 496) whatever the latter's position, prevent leakage from the external opening.

In man, samples of intestinal contents can be obtained by means of the Millar-Abbot tube.

The composition of intestinal juice varies greatly under different conditions. At times it consists chiefly of water and salts and has a low digestive power. At other times it is slimy from

Peptidases, erepsin

The peptids that have resisted pancreatic digestion are finally broken up into the separate amino-acids by peptidases in the intestinal juice. The juice contains several peptid-splitting enzymes, each with a specific action upon a particular type of peptid. The *succus entericus* is almost powerless to attack native protein or peptone, the protein must first have been partially digested by trypsin and have reached the peptid stage. The peptid-splitting action of the intestinal juice has until recent years been attributed to a single enzyme to which the name *erepsin* was applied by Cohnheim. The intestinal mucosa itself is rich in peptidases;⁴ their presence here would appear to afford a safeguard against the entrance of incompletely split products of protein digestion into the blood stream. Peptidases are also found widely distributed, though to variable extent, throughout the tissues of the body, as well as in various plants, yeast and even in bacteria. They are also present in low concentration in pancreatic juice. The optimum pH for the reaction of the peptidases of the *succus entericus* is around 8.0.

The intestinal wall also contains such enzymes as *nucleases*, *nucleotidases* and *nucleosidases* (p. 565). The first of these hydrolyse nucleic acids into their constituent nucleotides; the nucleotidases split the nucleotides into nucleosides and phosphoric acid; the nucleosidases separate the nucleosides into sugar (pentose) and purine bases. *Arginase*, a ferment which splits arginine into ornithine and urea (p. 546) is also present in the intestinal mucosa as well as in the liver and other tissues. *Phosphatase* (p. 716) is found in relatively high concentration in the mucosa of the small intestine.

Ferments which act upon sugars

If we except the small amounts of maltase contained in saliva and pancreatic juice, and the comparatively slight change that the HCl of the gastric juice exerts upon cane sugar, then the responsibility for the digestion of the disaccharides devolves entirely upon ferments in the *succus entericus*. *Maltase*, *sucrase* (also called *invertase*)

⁴ Though it is generally stated that these and the other enzymes in fistula juice are *secreted* it must be admitted that the experimental conditions under which the juice is collected do not exclude the possibility that its activity is due to enzymes liberated from disintegrated cells of the intestinal mucosa. Some indeed hold the view that under physiological conditions only enterokinase and amylase are actually secreted in the *succus entericus*.

FIG. 196. (From Maximow and Bloom, after Schaffer.)

the presence of a large proportion of mucus. Its concentration in ferments varies considerably. It owes its alkaline reaction (pH from 7.0 to 8.5) to the presence of *sodium carbonate* and *bicarbonate*. It contains *enterokinase*, the activator of trypsin (p. 449).

The chief ferments of intestinal juice are;— (1) *Various peptidases (erepsin)*; (2) A ferment for each of the disaccharids, *sucrose* (cane sugar), *maltose* (malt sugar) and *lactose* (milk sugar); (3) *Lipase*; (4) *Amylase* in traces.

and *lactase* are powerful enzymes which act specifically upon the corresponding substrates to convert them into monosaccharides. A molecule of maltose is converted by maltase into two molecules of the hexose, glucose, by a process of hydrolysis according to the equation—

Similarly sucrose is split into a molecule each of glucose and fructose by *sucrase*.

Lactase converts lactose (milk-sugar) into the hexoses glucose and galactose. The enzymes acting upon the disaccharides are also present in the tissue of the intestinal wall.

Lipase

The intestinal juice contains small but not unimportant quantities of lipase; relatively large amounts of fats are digested in the absence of the pancreas or after ligation of its ducts. Fifty per cent or more of the ingested fat may undergo hydrolysis under these circumstances.

The various digestive ferments are secreted in much smaller amounts in the lower reaches of the small intestine, and in the large bowel the secretions are composed mainly of water, mucus and inorganic salts; ferments are almost entirely lacking.

THE SECRETION OF INTESTINAL JUICE

The intestinal juice is secreted continuously though in variable quantities from time to time. The activity of the intestinal glands is under *nervous and hormonal* influences.

Nervous influences. Mechanical stimulation

The glands respond very promptly and energetically to mechanical stimulation of the intestinal mucosa. The secretion then is brought about reflexly through the nerve plexuses within the bowel wall. Juice drains continuously from a loop of bowel opening to the exterior and division of the extrinsic nerves does not reduce the secretion resulting from mechanical stimulation (e.g., distention). The secretion indeed is more likely to be increased by sympathetic denervation of the loop, an observation which suggests the removal of an inhibitory influence. An experiment performed by Moreau has also led to the belief that

the sympathetic nerves exert an inhibitory effect upon secretion. This observer obstructed the bowel at three points by means of ligatures, thus forming three closed loops. The central loop was denervated. The intestine was replaced within the abdomen and the latter closed. Upon examining the loops in from four to sixteen hours later, the central loop was found distended with intestinal juice while those on either side were comparatively empty. It is possible, however, to explain this result upon a vascular basis—namely, the loss of vasomotor tone and consequent hyperemia of the denervated loop—without assuming that an inhibitory influence upon secretion had been removed.

Experimental stimulation of the vagus nerve has on the whole given inconclusive results; Wright and his associates have reported that vagal stimulation causes secretion from the upper part of the duodenum but from no other part of the intestine if the sympathetics were intact. After section of the sympathetics in the thorax a secretion from the intestine followed stimulation of the vagus.

As a result of the sensitivity of the mucosa to mechanical stimuli, undigested food residues or other unabsorbable solid material will in their passage through the bowel cause excitation of the glands and so increase the fluidity of the intestinal contents. The advantage of this in aiding the movement of food along the alimentary canal is obvious.

Hormonal influences

It is probable, though it has not been definitely proved, that secretin serves as a stimulant for the secretion of intestinal juice as well as for pancreatic secretion; according to Florey and Harding it excites the glands of Brunner. Injection of secretin into the blood stream has been reported to cause secretion from a Thiry fistula; the secretory effect is unaltered by denervation of the loop of bowel. Secretion into an isolated loop has also been observed when acid was placed in a second loop. The secretion was due presumably to the passage of secretin into the general blood stream. Pancreatic juice acting locally within the bowel lumen, according to Pavlov, also excites the intestinal glands. The juice which results is rich in enterokinase. Pancreatic juice injected into the blood stream has no such effect. Nasset and associates have isolated a substance from the mucosa of the small intestine which they believe is a specific hormone controlling the secretions of the intestinal glands. This substance, which

they have named *enterocrinin*, is free from vasodilator effects and does not stimulate pancreatic secretion. It is prepared from extracts of the small and large intestine; it increases both the volume and enzyme concentration of the succus entericus.

Secretion of mucus

Mucus is secreted by the epithelial cells (goblet cells) of the small intestine and colon. Florey in experiments upon cats concluded that the secretion of mucus by the colon was not under nervous control. Prolonged stimulation of parasympathetic fibers (pelvic nerve) or of the sympathetic was without effect. Pilocarpine, a parasympathetic drug, is also ineffective unless administered in relatively enormous doses. Mechanical stimulation of the mucosa or the application of chemical irritants, e.g., silver nitrate, mustard, iodine, or high temperature, causes a pronounced secretion of mucus. The secretion is brought about, it is believed, by direct stimulation of the goblet cells which increase in number progressively from the upper to the lower regions of the intestinal tract. The injection of histamine, acetylcholine, adenosine or peptone solutions which cause vasodilatation did not cause secretion. The chief functions of the mucus secreted by the colon are to protect the mucosa from injurious agents and, under certain circumstances, by lubricating the intestinal lining, to aid the movement of feces.

A great increase in the production of mucus by the colon is an outstanding feature of the condition known as *mucous colitis*. Abdominal pain, spastic constipation intermitting with attacks of diarrhea and the passage of masses of mucus characterize the disease. Its cause is obscure.

THE BILE

In most animals and in man, bile is secreted continuously by the liver cells. It passes along the bile capillaries, hepatic and cystic ducts to be stored in the gall-bladder. Its expulsion from the latter and its passage along the common duct into the duodenum is intermittent, related in time to the arrival of food in the intestine, and is quite independent of the actual secretion by the liver (see p. 473).

THE COMPOSITION OF THE BILE

The bile is a highly complex fluid. The physiological significance of many of its constituents is unknown; some are present only in minute amounts and are most probably merely waste products undergoing elimination. Table 34 gives the com-

position of human liver bile (parts in 1000), as analyzed by Hammarsten. Liver bile has a pH of between 8.0 and 8.6. The reaction of human gall-bladder bile is neutral or slightly alkaline; that of the dog (or cat) is definitely acid—pH between 5.0 and 6.0. The chief biliary components are the *bile salts*, *bile pigments*, *cholesterol* and *lecithin*. These organic materials make up over 60 per cent of the total biliary solids. As a result of the absorption of water and inorganic salts (p. 471) gall-bladder bile is several times more concentrated in organic solids than liver bile. The biliary constituents may vary independently of one another.

The bile salts

The bile salts are the *glycocholate* and *taurocholate of sodium*. The bile acids glycocholic ($C_{26}H_{47}NO_6$) and taurocholic ($C_{26}H_{45}NSO_7$) with which the base is combined, are formed by the

TABLE 34

junction of *glycocoll* (glycine) and *taurin* ($C_2H_7NSO_3$), respectively, with *cholic acid* ($C_{24}H_{45}O_6$). The glycocholic and taurocholic acids are present in about equal amounts in the bile of the herbivora and of man. Taurocholic is the sole acid in the bile of the dog and other carnivora. Taurin is related to cysteine, a sulphur-containing amino-acid; glycine we are familiar with as the simplest amino-acid and one which can be synthesized by the body (p. 545). Glycocholic and taurocholic acids therefore contain nitrogen, but sulphur is present in the latter only. The structural formula of cholic acid contains the tetracyclic carbon group characteristic of the sterols; this is shown below in skeleton form:

Cholic acid is therefore related to cholesterol, to the male and female sex hormones (Chapter lxii) and to corticosterone (p. 692). There is no evidence, however, that in the body cholic acid is derived from cholesterol; feeding the latter causes no increase in the production of bile salts. The physiological relationship between cholic acid and the sex hormones is obscure. The precursors of cholic acid in the body are also unknown.

Nor can much be said concerning the *site of origin* of the cholic acid; whether it is formed by the hepatic epithelium, or is merely brought preformed to the liver from other body tissues is not known. That some is formed in the body is indicated by the fact that the bile salts continue to be discharged from a biliary fistula during long periods of starvation. That it is derived also from the food appears from the observation that increased excretion follows the ingestion of protein material. Though the supplies of glycocol and taurine within the body are apparently plentiful the supply of cholic acid is limited, for experiments in which taurine was fed alone caused no increase in the excretion of bile salts whereas cholic acid ingestion alone caused a rise in the excretion of taurocholic acid. It is possible to deplete the taurine stores by feeding cholic acid for several days to a dog with a biliary fistula. When cystine disulphoxide, cysteine, cysteine sulphinic acid or cysteic acid is then fed with cholic acid, an increase in the taurocholic acid of the bile follows (Virtue and Doster-Virtue). This result suggests that from such or similar compounds, taurine is produced in the body. That is, taurine under these circumstances is evidently supplied from body sources whereas cholic acid must be furnished in the diet. The quantity of cholic acid available apparently determines the level of bile acid excretion (Whipple).

So far as is known the liver is the only situation where the *conjugation* of taurine or of glycocol with cholic acid, and the production of the respective bile acid can take place. The following observations suggest that their formation is a specific function of the liver. (1) When the function of the liver is depressed by injury, or by the establishment of an Eck fistula (p. 287), the output of bile salts may be reduced by 50 per cent or more (Smyth and Whipple). (2) When the common bile duct is ligated in dogs bile acids appear in the blood. On the other hand, no accumulation occurs in the blood after removal of the liver. The liver is also the site for the destruction of bile salts, for when fed they can be recovered quantitatively from the urine of hepatectomized but not of normal animals.

THE CIRCULATION OF THE BILE SALTS. After their passage into the intestine, the bile salts undergo re-absorption and are carried in the portal blood stream back to the liver for re-excretion. This portal-biliary circulation of the bile salts is

intimately connected with the absorption of fat (p. 599). When bile salts are fed to an animal they can be recovered almost quantitatively from a biliary fistula. This indicates that in the intact animal the re-absorption of bile salts is almost complete (about 90 per cent). Under ordinary circumstances comparatively small amounts (about 10 per cent) of bile salts are formed afresh, i.e., their concentration in the bile is maintained largely as a result of their being circulated over and over again through the portal and biliary systems. Nevertheless, if the bile be prevented from entering the intestine by draining it to the exterior through the fistula, its concentration in bile salts does not become materially reduced. Berman and his associates found that, in dogs which lost all their bile through a fistula, about 0.5 gram of cholic acid was excreted in 8 hours. These facts indicate the existence of some unknown mechanism controlling bile salt production.

Tests for bile salts. Pettenkoffer's test. Five cubic centimeters of the fluid to be tested are mixed in a test tube with a few drops of a 10 per cent solution of cane sugar. A cubic centimeter or two of concentrated sulphuric acid are introduced beneath the surface of the mixture. The appearance of a red ring at the junction of the two liquids indicates the presence of bile salts; upon agitation the color diffuses through the solution. The color is due to the formation of cholalic acid from the bile acids and its combination with the furfural resulting from the decomposition of the cane sugar. A few drops of a 1 in 1000 aqueous solution of furfural itself may be employed (Mylin's modification) instead of the sugar solution.

Rowntree and associates have developed a method for the quantitative estimation of bile salts in blood based upon the Pettenkoffer reaction. The bile salts are extracted from the blood with alcohol and the test performed upon the extract. The color is compared in a colorimeter with that produced under similar conditions in a standard solution of pure glycocholic acid. The results are expressed in terms of glycocholic acid. Normal human blood contains from 2.5 to 6 mg. per cent of bile acids. In obstructive jaundice the value is increased, sometimes several fold.

Hay's test is based upon the property of the bile acids to lower surface tension (p. 462).

The bile pigments

The biliary pigments are *bilirubin* and *biliverdin*. Bilirubin ($C_{43}H_{66}N_4O_6$) is the chief pigment in human bile and in the bile of the carnivora. Biliverdin ($C_{43}H_{66}N_4O_6$) is an oxidative derivative of bilirubin and is present only in small amounts in human bile but is the chief pigment of birds'

bile. The pigments constitute from 15 to 20 per cent of the total solids in liver bile.

The readiness with which the bile pigments are oxidized and the color changes which they undergo in the process are the basis for Gmelin's test for bile in body fluids. If, for example, a fluid containing bile be passed through filter paper, and a drop of fuming nitric acid be then dropped upon the wet surface of the filter, the pigment is oxidized and a series of concentric rings of different colors appears—yellow, yellowish-red, violet and blue-green from within outwards. Besides biliverdin other derivatives of bilirubin are found in the body. *Urobilinogen* (cf. below and p. 460) is a reduction product of bilirubin; upon oxidation it yields *urobilin*. *Bilicyanin* and *bilifuscin* are formed by the oxidation of biliverdin. The latter two pigments are not found in bile but may be present in gallstones. *Biliprasin* is an intermediate product formed in the oxidation of bilirubin to biliverdin.

THE ORIGIN OF THE BILE PIGMENTS. Bilirubin is derived from hemoglobin, being the porphyrin (globin-free and iron-free) fraction of the hemoglobin molecule (p. 40). Any condition which leads to an increased destruction of red cells (hemolysis) causes a greater production of bile pigment. The chemical relationship between hemoglobin and the various bile pigment derivatives is shown schematically below.⁶

THE SITE OF BILIRUBIN FORMATION has been a subject of controversy for many years and it is only recently that the question has been answered definitely. The discovery, in old extravasations of blood, of a pigment with the chemical properties of bilirubin, was one of the first observations to throw doubt upon the view then prevailing, namely, that the liver was solely responsible for bile pigment formation. This pigment was called

⁶ Lemberg's researches point to a different sequence of chemical changes. He finds that hemin (derived from hemoglobin, p. 40), first yields biliverdin which then undergoes reduction to bilirubin.

⁶ Myoglobin (p. 43) and possibly pigment constituents of the diet may also as a source of bilirubin.

hematoidin (Virchow); the significance of its discovery lay in the fact that the old blood clots in which it was found were in situations remote from the liver. Hepatectomy in geese—which is a relatively simple operation on account of the anatomical peculiarities of the avian liver—was performed by Minkowski and Naunyn with the object of finding a definite answer to the question of the site of bile pigment production. Arseniuretted hydrogen, a powerful hemolytic poison, when injected into normal birds caused the accumulation of bile pigment in the blood. No such effect followed injection of the poison into hepatectomized birds. This apparently crucial experiment indicated that the liver alone was capable of forming bile pigment. McNee some years later repeated this experiment and obtained the same results, but he suggested that the reticulo-endothelial elements of the liver (Kupffer cells) rather than the true secretory cells were responsible. Investigations upon this subject within more recent years have proved conclusively, however, that in mammals the liver is not essential for bile pigment formation. Whipple and Hooper, employing dogs, attempted to isolate the liver from the general circulation. Bilirubin was found in excess in the circulating blood, a result diametrically opposed to the results obtained with

birds. The method employed by these investigators for the isolation of the liver has been criticized, but nevertheless the conclusion which they reached, namely, that tissues other than the liver have the ability to produce bile pigments has been substantiated by Mann, Bollman and Magath, and is now universally accepted. These observers removed the liver completely from dogs (p. 287). The animals survived for 24 hours or more; bilirubin commenced to appear in the blood in from 3 to 6 hours after the operation⁷ and gradually increased in amount up to the time of

⁷ Dog's plasma normally does not contain appreciable amounts of bilirubin.

death. The injection of hemoglobin into the circulation increased the bile pigment accumulation. Mann and his associates also showed by spectroscopic methods that the blood of the splenic vein of a normal animal has a higher bilirubin concentration than that in the corresponding artery.

It is now accepted that the elements of the *reticulo-endothelial system* (see p. 78) situated in various parts of the body, spleen, lymph glands, bone marrow and the general connective tissues, as well as in the liver, are responsible for the formation of bile pigment. Of these, the bone marrow is probably the most important. In an animal deprived of both spleen and liver, bilirubin continues to be formed at approximately the normal rate.

A certain amount of bilirubin is normally present in human serum, (from 0.2 to 0.8 mg. per 100 cc.) as a result of the transformation by the reticulo-endothelial elements of hemoglobin liberated from broken down red cells (p. 56). It has been estimated that 1 gram of hemoglobin yields 40 mg. of bilirubin. The iron which is freed from the hemoglobin is stored mainly in the liver (p. 58) but also to some extent in the spleen. It has been shown by Rich that the hemoglobin-bilirubin transformation effected by the reticulo-endothelial structures is an intracellular process. When fresh red cells were cultured with the reticulo-endothelial cells the former were destroyed, and in a short time typical crystals of bilirubin, and in some cases biliverdin, were found to have formed within the phagocytes. In some instances iron deposition within the cells and adjacent to the crystals could be detected by means of the Prussian blue reaction.

The results of the earlier experiments of Minkowski and Naunyn are explained in the light of these discoveries. The reticulo-endothelial system of the bird is practically confined to the liver. When the liver was excised all the cells capable of forming bile pigment were therefore removed.

There is no evidence that the true secretory cells of the liver play any part in the formation of bilirubin. They merely excrete the pigment that reaches them preformed.

UROBILINOGEN, UROBILIN; THE CIRCULATION OF BILE PIGMENT. The bilirubin that enters the intestine undergoes reduction by bacteria to form *urobilinogen* (also called *stercobilinogen*). A part of this is excreted in the stools and by oxidation is converted to *urobilin* (*stercobilin*). The latter can be detected spectroscopically or by the green

fluorescence which it gives with a solution of alcoholic zinc acetate. A certain proportion of the urobilinogen is reabsorbed into the portal circulation, passes to the liver, and is almost completely re-excreted in the bile (fig. 197). Any urobilinogen which may escape into the general circulation and be excreted by the kidney becomes oxidized to *urobilin* after the urine has been voided. Normally, however, no urobilin or mere traces (0.5 to 2 mgm.) appears in the urine. Bilirubin itself does not appear normally in the urine, so the color of urine is due to neither of these pigments (p. 398). That the urobilinogen normally present

FIG. 197. Diagram illustrating the formation of urobilinogen from bilirubin in the intestine, its excretion in part in the feces and its absorption in part into the portal blood. Normally, the absorbed pigment except in negligible amounts is practically all re-excreted in the bile. The dotted lines indicate its passage into the blood, and its excretion by the kidney in cases of liver damage, excessive blood destruction or in the early stages of obstructive jaundice.

in bile merely represents re-excretion of this pigment after its absorption from the intestine was clearly shown by Elman and McMaster. When the entire output of bile was collected through a fistula (i.e., none was allowed to enter the intestine) there was complete disappearance of urobilinogen from the bile after the pigment already present in the intestine had been carried away in the feces. The fistula bile remained free from urobilinogen unless infection of the biliary tracts had occurred, under which circumstance bacterial action in these situations caused its formation. When a part of the bile was allowed to enter the intestine or bile was fed by mouth the derived pigment invariably appeared in the fistula bile.

Also, complete experimental obstruction of the

common bile duct, since it prevented the re-excretion of the urobilinogen absorbed from the intestine, resulted in its accumulation in the blood and its excretion in the urine. These effects however, can only occur for a short time after the duct has been obstructed, and are due to the absorption of pigment remaining in the intestine from the period prior to obstruction. After the pigment has been cleared from the intestine, the urine, though it may contain large amounts of bilirubin, is quite free from the derived pigment. Depression of the excretory function of the liver by such poisons as chloroform, phosphorus, etc. caused urobilin to appear in the urine, even though the injury was slight and there was no bilirubinuria. When bilirubin formation was increased by hemolytic agents urobilinogen production was also increased; the liver even though its function was normal was unable to re-excrete the excess pigment absorbed from the intestine, and urobilin appeared in the urine.

Urobilinogen is in rare instances formed in situations other than the intestinal tract and independently of bacterial action. Rabinowitch, for example, has reported a case in which large quantities of urobilinogen were present in the urine. A sterile ovarian cyst containing an old blood clot and a high percentage of urobilinogen was revealed by operation. When the cyst was removed the urobilinogen disappeared from the urine.

Lecithin and cholesterol

Lecithin is present in human liver bile to the extent of from 0.02 to 0.05 per cent. The *cholesterol* content is normally from 0.04 to 0.16 per cent. The cholesterol is present in the free state, i.e., not in the form of esters. The percentages of these materials in the bile of the gall-bladder is, as a result of the absorption of water and salts through the gall-bladder mucosa, much higher than the percentages in liver bile. The ratio of the concentration of cholesterol in bile to that of the bile salts is from 1:20 to 1:30. The ability of the bile to hold cholesterol in solution is in large degree dependent upon the bile salts. If the ratio falls to 1:13 precipitation of cholesterol occurs. Andrews and associates showed that if bile be dialysed against water, bile salts are removed and the bile becomes turbid as a result of cholesterol precipitation. The importance of this observation in relation to gallstone formation is considered on page 467. The fatty acid concentration of the bile is of as great if not greater importance than the bile salt concentration in

holding cholesterol in solution. Little is known concerning the origin and function of the biliary cholesterol. It may be derived from the stroma of disintegrated red cells or from nervous tissue, which of course contains it in large amounts. According to Gardner the cholesterol of the bile does not vary with changes in the total blood cholesterol, nor is its concentration raised by increasing the cholesterol content of the diet; it continues to be excreted upon a cholesterol-free diet. A biliary-portal circulation of cholesterol has been shown to occur, i.e., excretion in the bile, re-absorption from the intestine and re-excretion by the liver.

THE FUNCTIONS OF THE BILE

Besides serving as a vehicle for the excretion of pigments and certain other waste products from the body, the bile performs important functions in the intestine.

The rôle of the bile in fat digestion

Bile is essential for the efficient digestion of fat by the pancreatic and intestinal juices, yet the bile itself contains practically no lipase or indeed any other digestive enzyme. The absence of any lipolytic action on the part of the bile is illustrated by the observation of Claude Bernard made upon the lymph vessels of the rabbit's intestine at the height of digestion. In this animal the pancreatic duct opens into the intestine 10 cm. or so below the orifice of the bile duct. After a meal the lymph vessels in the intervening area were quite clear, but those below the pancreatic duct were milky with absorbed fat. The importance of bile, nevertheless, in fat digestion (and absorption) was shown by the following experiment. When the orifice of the bile duct in the dog was transplanted into the intestine a short distance *below* the pancreatic duct the lymph vessels in the space separating the ducts were free from fat, while those below the transplanted bile duct were milky. The coadjutant action of the bile upon fat digestion is also shown by the fact that, if the bile is prevented from entering the duodenum, either by experimental ligation of the common bile duct in animals, or in man as a result of obstruction of the duct by a stone or by its obliteration in any other way, fat digestion is imperfect, a proportion of the fat of the food being excreted unchanged in the feces. The important aid which bile lends to the digestion of fat is due to the bile salts. The influence of the bile salts is exerted in two ways.

First, they aid emulsification to a marked degree, the fat globules are reduced in size, and in consequence, a finer and more stable emulsion results. In this way the total surface area of the fat exposed to the action of pancreatic lipase is enormously increased. This action depends mainly upon the property possessed by the bile acids of lowering surface tension. Upon this property is based Hay's test for the detection of bile in urine. Flowers of sulphur float upon the surface of normal urine but sink if bile be present. The bile salts have also a *hydrotropic action*, i.e., they render water-insoluble materials such as fatty acids and calcium soaps readily soluble in the watery fluids of the intestine. Some of these fatty acids when free in solution aid the emulsification process since they too have the property of lowering surface tension. Their combination with alkali to form soaps—the extent to which this occurs being dependent upon the reaction of the intestinal contents—also, and for the same reason, furthers emulsification. The cholesterol of the bile acts as an adjuvant to the bile salts in the emulsification process.

Secondly, the bile salts (by virtue of the cholic acid radical) act as specific activators of pancreatic lipase; the latter enzyme has only a weak action in their absence. They also act in a similar manner, though to a less degree, upon gastric lipase, have no effect apparently, upon the fat-splitting enzyme of the intestinal juice. That this action of bile is distinct from its effect in furthering emulsification is shown by the fact that the hydrolysis by pancreatic lipase of triacetin, which is *soluble* in water, is also accelerated by the bile salts.

The rôle of bile in fat absorption

Fat digestion although seriously impaired may be carried on to a considerable extent in the intestine after removal of the pancreas and ligation of the bile duct; the lipase of the intestinal juice is then chiefly responsible for the cleavage of the fat molecule. Gastric lipase, especially if the intestinal contents are definitely acid in reaction, may also aid to some extent. Certain bacteria in the colon have a lipolytic action and they may account for a considerable quantity of fat being split in the large intestine. In obstruction of the bile ducts alone the greater proportion of the fat is split, over 80 per cent of the fecal fat being in the form of fatty acids. The *absorption* of fat, on the other hand, is very greatly interfered with under these circumstances, only a small proportion of ingested fat being utilized. Bile is therefore of much greater importance for fat absorption than for fat digestion. According to Verzár the fatty acids unite with the bile salts to form com-

plex compounds; as such the greater part of the fat is absorbed from the intestine.

The solvent action of the bile salts upon cholesterol has been mentioned (p. 461). Bile is also necessary for the absorption of vitamin D; the essential constituents for this action being, apparently, the bile salts. Graeves and Schmidt found that the calcium balances of dogs with biliary fistulae became negative but were restored to normal by the subcutaneous injection of vitamin D. Taylor, Weld and Sykes noted that a rise in the serum calcium could not be induced in dogs with biliary fistulae by the oral administration of irradiated ergosterol but that this substance exerted its usual effect when given intravenously, or by mouth if combined with bile or bile salts (see also p. 466). With regard to the other fat-soluble vitamins, vitamin K and probably vitamin E also fail to be absorbed in adequate amounts in the absence of bile. Bile is necessary for the absorption of carotene though not for vitamin A itself.

OTHER FUNCTIONS have been ascribed to the bile, but they are based upon a less sure foundation than those that have been discussed. Among these are (a) *antiputrefactive*. This action is probably secondary in nature and not due to any direct inhibitory effect of the bile upon bacterial growth. Indeed it has been shown that bile will serve as a suitable culture medium for microorganisms, and the contents of the gall-bladder apparently are readily infected. However, in the absence of the bile putrefactive processes in the intestines are no doubt more active, but this is probably due to the protective covering which the undigested fat affords for protein material; the growth of proteolytic bacteria is thereby encouraged. (b) *Laxative*. Bile when introduced directly into the rectum or colon stimulates peristalsis. It is also stimulating to the movements of the small bowel, but the constipating effect which follows the exclusion of bile from the intestine is probably brought about mainly indirectly, the unsplit fat inhibiting intestinal motility. (c) Bile appears to possess a function apart from all those mentioned which is essential to life. Whipple found that bile fistula dogs develop abnormalities of the bones, associated with a loss of inorganic constituents. They eventually succumb unless bile is fed.

THE SECRETION OF BILE

It will be recalled that the secretion of bile by the polygonal cells of the liver and its passage along the biliary channels for storage in the gall-bladder is a continuous process. The intermittent discharge of bile from the gall-bladder will be considered in Chapter XLII. Several substances

stimulate biliary secretion. Materials which act in this way are known as *cholagogues*.⁸ The natural and the most powerful excitants of biliary secretion are the bile salts themselves. *Secretin* is also a physiological stimulus of biliary secretion (p. 451). Meat or fat in the diet stimulates the flow, whereas sugar is inhibitory. In starvation the volume of the secretion is reduced by about half. Drugs such as podophyllin, aloes, acids and several other chemicals which have enjoyed a reputation as cholagogues, were found by Whipple and his associates to have no notable effect upon biliary secretion. Calomel and ammonium chloride are without any significant effect, but salicylates and linseed oil are definitely stimulating. Adrenaline decreases the flow, whereas pilocarpine and prostigmine increase it. The rate of secretion in man (bile fistula) on an ordinary diet averages around 23 cc. per hour during the waking hours and 15 cc. per hour in sleep—a total volume of around 500 cc. daily.

The bile is capable of being secreted under a pressure of from 250 to 300 mm. of water. If a manometer be placed in the common duct the secretion of bile ceases when the pressure reaches this height and shortly afterward jaundice appears. Under ordinary physiological conditions the sphincter surrounding the opening of the common duct into the duodenum is kept tonically closed. The duct system fills with bile and when the pressure rises to from 50 to 70 mm. H₂O the fluid passes along the cystic duct into the gall-bladder. As a result of the pressure-regulating function of the gall-bladder (p. 473) the maximal pressure in the biliary canal system is not attained after obstruction of the common duct in animals until a considerable time has passed. Mann found that jaundice did not develop after this operation in dogs until the lapse of from 48 to 72 hours.

Bile secretion is under vagal control, stimulation of the peripheral end of the vagus (in dog or monkey) causing a very definite increase in bile production (Tanturi and Ivy). Snyder found that an acetylcholine-like substance appeared in the hepatic veins upon vagal stimulation. A reflex secretory effect can also be demonstrated by

⁸ This is a very old term dating from the time of Galen and refers to increased flow of bile into the intestine which, of course, may be due either to increased secretion or to discharge from the gall-bladder. It has been suggested recently that the word cholagogue be used to indicate a stimulating action upon the discharge of bile from the gall-bladder, and the term *choleresis* to denote increased secretion by the liver.

stimulating the central cut end of one vagus. Bile secretion is inhibited reflexly by distension of the colon and by stimulation of the sympathetic. This latter effect is probably secondary to a constrictor effect upon the hepatic vessels. The vagus in the dog also contains some fibers which inhibit secretion. There appears also to be a psychic secretion of bile.

JAUNDICE

DEFINITION AND CLASSIFICATION

When bile pigment is present in excessive amount in the blood (hyperbilirubinemia) it escapes into the tissues, e.g., skin, mucous membranes and conjunctivae which then become stained a yellow tint. The condition is termed *jaundice* or *icterus*. The bilirubin appears in the urine and sweat but does not pass into the saliva or milk, nor as a rule into the cerebrospinal fluid.⁹ Jaundice may be due to the production of bile pigment in excess of the amount with which the excretory power of the normal liver can cope. Or, it may result from the failure of a damaged liver to excrete the bilirubin produced in normal amounts. In either case bile pigment accumulates in the blood and when it reaches a certain degree of concentration diffuses into the tissues to give the characteristic discoloration. Jaundice may therefore be divided into two main groups corresponding to the mode of its production. These are, the *hemolytic* and the *hepatic*, the former resulting from increased production of pigment, and the latter from depressed or suppressed excretion of pigment by the liver. In the hepatic form the retention of pigment may be due to (a) obstruction of the bile passages or (b) damage of the liver cells by toxic agents or infections. Jaundice is also sometimes classified into obstructive and non-obstructive, the latter being subdivided into hemolytic, on the one hand, and toxic or infective on the other. These principal varieties of jaundice are tabulated below.

Hepatic	1. Hemolytic jaundice	} non-ob- structive
	2. Toxic, or infective jaundice	
	3. Obstructive jaundice	

HEMOLYTIC JAUNDICE

It has already been mentioned that a small amount of bile pigment (0.2 to 0.8 mg.) per cent

⁹ Its appearance in the cerebro-spinal fluid is not uncommon in children.

is present in normal human serum and that any condition which increases red cell destruction also increases the formation of bile pigment. Unless the over-production of bile pigment is very great the healthy liver, which possesses a large functional reserve, is able to meet the extra demand, but when the disintegration of red cells is such that the balance between production and excretion of pigment cannot be maintained even by the normal liver, the bilirubin concentration in the blood rises above the normal limits. *Hemolytic agents* of all sorts, such as the toxins of certain infections, septicemia, etc., and various chemical poisons may induce icterus (p. 49) of this type. It also occurs to some degree in such states as *pernicious anemia*, *malaria*, etc., in which blood destruction is a pronounced feature. It may be produced in animals by the injection of such hemolytic poisons as toluylendiamine and arseniuretted hydrogen. The disease known as *acholuric jaundice* which tends to run in families and is associated with splenic enlargement and increased fragility of the red cells (p. 61), is of this type. Jaundice in the new-born, *icterus neonatorum*, (*benign*) frequently occurs as a slight transient staining of the skin and is most probably the result of the destruction of the red cells that are in excess at birth (p. 8). It is perfectly innocent and indeed may be considered physiological. It does not appear until a day or two after birth and lasts for five or six days.

OBSTRUCTIVE JAUNDICE

Obstructive jaundice results from blockage of the hepatic or common bile duct by (a) a gallstone or parasites within its lumen, (b) compression of the duct by a tumor (e.g., in head of pancreas) or occlusion of its opening into the duodenum, (c) congenital obliteration of the ducts (a fatal form of *icterus neonatorum*).

In complete biliary obstruction the stools are clay-colored; urobilinogen (p. 460) is absent from the feces and urobilin from the urine. The jaundice resulting from obstruction is not due to the re-absorption into the blood or lymph vessels of bile which has been secreted into the obstructed passages, but to the suppression of secretion. After obstruction, secretion continues only for a short time, or until the pressure in the ducts equalizes the secretory pressure of the liver cells (250 to 300 mm. H₂O). In obstructive jaundice the bile pigment is believed to pass from the blood into the liver cells, but instead of being secreted into the bile capillaries, it is absorbed into the

hepatic veins and lymphatics. McMaster and Rous found, for example, that when obstructive jaundice was induced in dogs, the occluded duct after a time became filled with a fluid free from pigment and bile salts—the so-called *white bile* (p. 472). According to these observers the colorless fluid is secreted by the membrane lining the ducts.

The excretory mechanism of the liver has been shown by McMaster and Rous to possess a large reserve since, in the dog, jaundice does not develop until from 90 to 95 per cent of the excretory ducts have been occluded.

TOXIC AND INFECTIVE JAUNDICE—LIVER DAMAGE

Liver damage and consequent depression of secretory functions of the liver may be produced by: (a) various *poisons*, e.g., arsphenamine, phosphorus, chloroform, etc., (b) *acute and chronic liver diseases*, e.g., acute yellow atrophy, cirrhosis, inflammation of the bile passages (catarrh, jaundice, suppurative cholangitis); (c) *toxins* of various pathogenic bacteria; (d) engorgement of the hepatic vessels as a result of *cardiac failure*. It has been pointed out by Meakins that in the latter condition the edema or ascitic fluid does not contain bilirubin and the skin over edematous regions is not stained. There is no explanation of this fact.

Jaundice is frequently due to a combination of causes.

It should be pointed out that in any given case of jaundice two or all three causative factors may and frequently do, coexist. Blood destruction alone, according to Rich, is not capable of producing jaundice except perhaps in rare instances when the hemolytic process is of extreme degree. In pernicious anemia, for example, there is an associated hepatic insufficiency and even in the ordinary icterus of the new-born the immaturity of hepatic function is claimed to be a factor; also many hemolytic substances are liver poisons as well. In obstructive jaundice the liver cells suffer damage from pressure and the retention of bile salts probably induces a certain amount of hemolysis. Furthermore, in many inflammatory conditions of the bile ducts an obstructive element (due to plugging of the intra-hepatic ducts by the so-called *bile-thrombi*) exists in conjunction with the hepatic damage. In the jaundice of cardiac diseases the hepatic engorgement produces obstruction of the finer bile capillaries as well as injury to the liver cells through anoxemia. The occurrence of infarcts in the lung is also a factor.

some cases; bilirubin production is increased through the break-down of red cells in the infected areas.

CLINICAL TESTS EMPLOYED IN THE STUDY OF JAUNDICE

The van den Bergh reaction

This test—a modification of Ehrlich's diazo reaction—is employed for the detection of bile pigment in blood serum. There are two main types of the reaction—the *direct* and the *indirect*. The direct reaction occurs without the addition of alcohol, which is essential for the indirect reaction.

The REAGENTS used in the test are:

Solution A:

Sulphanilic acid.....	0.1 gram
Concentrated HCl.....	1.5 cc.
Water up to.....	100 cc.

Solution B:

Sodium nitrite.....	0.5 gram
Water.....	100 cc.

To perform the test 10 cc. of solution A and 0.3 cc. of solution B are freshly mixed. This mixture is used as the reagent in both forms of the test.

The *direct reaction* is that which follows the addition of 1 cc. of the reagent to 1 cc. of serum. It may occur in one of three forms, (a) *immediate* or *prompt*; a violet color due to the formation of diazo-bilirubin develops from 20 to 30 seconds. (b) *Delayed reaction*; no change appears until a minute or more has elapsed, when a reddish color develops which gradually deepens to violet. (c) *Bi-phasic*; a red color appears promptly in (a) but takes a variable length of time to change to violet.

The *indirect reaction* is carried out as follows. One cc. of serum is mixed with 2 cc. of 95 per cent alcohol. After shaking and centrifuging, to 1 cc. of the supernatant fluid, 0.25 cc. of the reagent mixture and 0.5 cc. of alcohol are added. A reddish-violet color develops almost immediately.

Normal bile and the serum in obstructive jaundice give the prompt direct reaction. Normal serum, the serum in hemolytic jaundice and the bilirubin formed from old blood extravasations into the connective tissues, serous cavities, etc., give only the indirect reaction. The sera in types of jaundice due to liver damage give a direct reaction (usually of the delayed or biphasic type) and sera which give the direct reaction also give the indirect.

The indirect reaction is used as the basis for the quantitative estimation of bilirubin in all types of sera. The serum after the color reaction has developed is compared in a colorimeter with a standard solution made by dissolving 2.161 grams of anhydrous cobaltous

sulphate in 100 cc. of distilled water. The color of this standard corresponds to that developed by 1 unit of bilirubin. A *unit* is defined by van den Bergh as 1 part of bilirubin in 200,000 parts of serum. Normal serum contains from 0.4 to 1.5 unit (i.e., bilirubin is present in a dilution of 1 part in from 500,000 to 100,000 parts of serum, or from 0.2 to 1.0 mg. per 100 cc.). In the quantitative estimation of bilirubin in sera showing the direct reaction the method has been rendered more accurate by the modification of Thannhauser and Anderson. This consists in first adding 0.5 cc. of the reagent to 1 cc. of the serum, and a minute or two later 2.5 cc. of alcohol and 1 cc. of a saturated solution of ammonium sulphate. By adding the diazo-reagent before the alcohol the loss of bilirubin which results from its being carried down with the albuminous precipitate is avoided. When the alcohol is added later the diazo-bilirubin compound is not thrown down but remains in the supernatant fluid.

The quantitative van den Bergh reaction is of value in the detection of latent jaundice, i.e., a hyperbilirubinemia which has not reached the level at which jaundice appears, and in recording the progress of a case of manifest jaundice.

The icteric index

The bile pigment concentration may also be estimated by comparing the color of the serum with that of a standard solution. A sample of blood is allowed to clot; after centrifuging, 5 cc. of serum are pipetted off and the color of the sample compared in a colorimeter with a 1 in 10,000 solution of potassium bichromate. The colorimeter is set at 15 mm. for the standard solution. This number is divided by the number on the serum scale when the color of the serum and of the standard solution match. The result is called the *icteric index*. Thus if the reading of the serum scale is 3 the icteric index is 5.

Galactose tolerance test of liver function

Galactose is converted into glycogen (though with considerable difficulty) by the normal liver. This sugar is therefore used as a test to distinguish jaundice due to obstruction from that primarily due to liver damage. The patient is fasted for 12 hours and then given 40 grams of galactose in 500 cc. of water. Normally or in jaundice of the obstructive type 3 grams or less are excreted in the urine within 5 hours. In jaundice due to liver damage the excretion amounts to from 4 to 5 grams or more during the first 5 hours.

THE FEATURES IN DIFFERENT TYPES OF JAUNDICE COMPARED

In obstructive jaundice and in jaundice resulting from liver damage, the staining of the skin, mucous membranes and urine with bilirubin tends

to be much more pronounced than in the hemolytic type. Except for a short time after the duct has been obstructed urobilin is absent from the urine and urobilinogen from the feces (p. 460). The plasma phosphatase (p. 717) is increased in jaundice due to obstruction or to liver damage but not in the hemolytic type. In obstructive jaundice the effects, e.g., *bradycardia*, *itching of the skin* (*pruritus*) and *reduced coagulability of the blood* referable to the retention of biliary constituents other than pigment may be evident. The cardiac slowing has been attributed to the action of the bile salts, though proof is lacking. Since the bile acids are conjugated in the liver it is not to be expected that their concentration in the blood will be raised in a purely hemolytic type of jaundice; this is found to be the case. On this account the latter type is sometimes spoken of as "dissociated jaundice." Also in severe liver damage bile acids may be absent from the blood though the hyperbilirubinemia is pronounced. In other instances of relatively mild degrees of hepatic insufficiency a converse type of "dissociated jaundice," namely, increased concentration of bile acids in the blood without icterus, is sometimes seen.

The bleeding tendency in obstructive jaundice is a serious hazard should a patient be required to undergo surgical treatment. Only within recent years, as a result of the work of Roderick, of Quick and his associates, and of Dam, has the cause of the prolonged coagulation time been discovered. It is due to prothrombin deficiency, which is the result in turn of a virtual lack of vitamin K (p. 90); in the absence of bile from the intestine the vitamin is not absorbed in adequate amounts. The oral administration of vitamin K with bile salts corrects the hemorrhagic tendency. Possibly an additional though minor factor in the lengthened coagulation time is the retention in the blood of certain organic sulphur-containing compounds (e.g., cysteine and taurine) possessing anticoagulant properties (Carr and Foot). Jaundice due to liver damage is also sometimes associated with a prolonged bleeding time and is then possibly due to the incapacity of the liver to manufacture the antihemorrhagic vitamin from a precursor in the diet. The cause of the pruritus in obstructive jaundice is unknown. Rowntree and associates found that though a high concentration of bile acids in the blood was frequently associated with pruritus this may occur with a normal bile-acid concentration or be absent when the latter is high.

In the non-obstructive types of jaundice (hemolytic, or those due to liver damage) urobilin may appear in the urine, and in the hemolytic types the excretion of urobilinogen in the feces is increased. The different van den Bergh reactions, namely, the direct in the obstructive and liver injury types of jaundice and the indirect in the hemolytic type are believed to depend upon some physical or chemical difference between the serum bilirubin in the two instances. It has been supposed that the differences depend upon whether or not the pigment has passed through the liver cells. In the obstructive and liver injury types (direct reaction) the pigment apparently takes this course. In the hemolytic type (indirect reaction), on the other hand, the retained bilirubin is that which the liver cannot dispose of and probably therefore does not enter the secretory cells. Several theories have been put forward in attempts to explain the difference in behavior of the two types of bilirubin toward the diazo-reagent. According to one view, the pigment giving the indirect reaction is combined with or adsorbed to some colloidal constituent (protein or lipid) of the serum which prevents it coupling with the diazo-reagent; alcohol is required to break the union. The direct reaction on the other hand, is due to bilirubin in the free state. It is suggested further that some substance supplied by the liver cells, possibly bile salts, is capable of breaking the union, thus accounting for the direct reaction given by normal bile and by the serum in obstructive jaundice.

Another explanation (Collinson and Fowweather) is based upon the view that bilirubin is an acid possessing two carboxyl groups. The direct reaction, it is claimed, is due to bilirubin in the form of an alkali salt (probably an ammonium salt or, according to Hunter, a monosodium salt). The alkali salt, being water-soluble, is able to react with the diazo-reagent. The indirect reaction, on the other hand, is due to the acid pigment itself which is insoluble in water but soluble in alcohol; the reaction between the diazo-reagent, which is also soluble in alcohol, can therefore take place. According to this view the bilirubin as formed by the reticulo-endothelial elements is conveyed to the liver cells where normally, or in obstructive jaundice, it is converted to the alkali salt.

Some of the differences between the properties of the two forms of bilirubin and certain observations relevant to the foregoing discussion are given below.

(a) The bilirubin of serum which gives the indirect reaction is oxidized less readily than that which gives the direct reaction (van den Bergh).

(b) The bilirubin giving the direct reaction is not extractable with chloroform, whereas the pigment giving the indirect reaction can be readily extracted by means of this reagent (Grunenberg).

(c) Serum giving the direct reaction gives the indirect reaction after heating for a short time (van den Bergh).

(d) The bilirubin in obstructive jaundice as shown by Blankenhorn and Hoover dialyses through a colloidion membrane, whereas the pigment of hemolytic jaundice does not. This observation is in accord with the fact already mentioned that the pigment in obstructive jaundice passes more readily into the tissues and urine than does that of the hemolytic type. In the former, staining of the skin and urine occurs when the serum concentration reaches 4 units (i.e., 1 part in 50,000 or 2 mg. per 100 cc.), whereas in the hemolytic type the concentration of bilirubin in the blood may be much higher than this without manifest jaundice.

(e) It has been shown by Barron that when a solution of pure sodium bilirubinate, which gives a direct reaction, is added to normal serum an indirect reaction is obtained. If, however, bile salts, sodium oleate or cholesterol be added to the serum together with the bilirubin the reaction becomes direct.

(f) When the bile salt concentration in the blood is elevated the serum may give a direct reaction though the serum bilirubin is within normal limits.

GALLSTONES—CHOLELITHIASIS

Gallstones are composed of constituents of the bile which have been thrown out of solution. Cholesterol is present in greater or less amounts in the commoner varieties of gallstone. Some stones may be composed almost entirely of this substance. In other types of stone, bile pigment or calcium is an important or the predominant constituent. Gallstones therefore differ considerably in size, color and inner structure according to the materials of which they are composed. They are classified according to their compositions into "pure" cholesterol, cholesterol-pigment-calcium, "pure" bilirubin, bilirubin-calcium and calcium carbonate stones. The latter are very rare in man but not uncommon in cattle. The "pure" cholesterol stone contains from 90 to 98 per cent of cholesterol, the remainder being made up of calcium, bile pigments, protein, etc. The "pure" pigment and the bilirubin-calcium stones, on the other hand, contain varying amounts of cholesterol. The cholesterol-pigment-calcium stone is the commonest variety. Stones of this type are usually multiple and, as a result of pressure of

one stone against another, show numerous facets upon their surfaces. They contain about 80 per cent of cholesterol which is deposited in cream-colored layers alternately with darker bilirubin-calcium laminae. The great majority of stones are formed in the gallbladder, but they may also form in the hepatic duct or even in the smaller ducts within the liver.

The formation of gallstones

The mechanism of gallstone formation is not clearly understood but the following are recognized as being the most important factors to be considered: (a) *Injury, especially of an infective nature to the gall-bladder wall*, (b) *disturbance in cholesterol metabolism*, (c) *stasis of the bile*, and (d) *reaction of the bile*.

(a) **INFECTION.** Following the classical work of Naunyn infection was looked upon as the main, if not the only, cause of gallstone formation. Naunyn maintained, and it is now current teaching, that the cholesterol of the bile was not dependent upon the cholesterol level of the blood and could not be altered by diet. He also claimed, however, that abnormalities of cholesterol metabolism played a minor rôle in the production of gallstones. The mucosa of the gall-bladder, he believed, normally secreted cholesterol and calcium and the secretory process was stimulated by any local inflammatory state. Experiments in which human cholesterol stones were shown to be dissolved after a time in the gall-bladder of the dog under sterile conditions, but not if infection were present, the production of gallstones by injections of microorganisms into the circulation after injury to the gall-bladder, and the frequent occurrence of cholelithiasis after infective conditions, notably typhoid fever, were all taken to indicate that infection was essential for the production of biliary calculi. The solvent action of the bile salts upon cholesterol was also held to support this view and to be against the suggestion that this biliary constituent could be thrown out of solution in the absence of infection. It was argued that the bile as it came from the liver could never have so high a concentration of cholesterol that simple deposition could result, but that the cholesterol must be produced in excessive amounts by an inflamed gall-bladder in order to be precipitated. Of the normal concentrating power of the gall-bladder little was then known (see p. 471).

Though not denying the importance of gall-bladder injury and the production of cholesterol from the inflamed mucosa in many cases of cholelithiasis, Aschoff and others have insisted that these conditions are not essential to the formation of calculi, and that certain types, especially the solitary cholesterol stone (see below), can arise in sterile bile and in the absence

of any diseased condition of the lining membrane. This view is now generally accepted. Much of the earlier work upon cholesterol metabolism to which Naunyn pinned his faith has been proved to be erroneous.

The multiple cholesterol-pigment-calcium stones are usually looked upon as typical infection stones. They are laminated on cross section and have usually a frame-work of coagulated protein. These stones are often very numerous, sometimes numbered by hundreds, and an examination of their structure indicates that they have all been formed at about the same time. According to Aschoff, the starting point of their formation is the deposition of pigment in the form of fine rosette-like structures upon which coatings of cholesterol, pigment and calcium are subsequently laid. The inflammatory exudate is rich in protein material derived from the blood, as well as in cholesterol and calcium. The protein, it is pointed out, carries an electric charge of opposite sign to that held by the cholesterol, pigment and inorganic constituents of the bile. It is believed that as a result of these physico-chemical relations the deposition of cholesterol combined in varying degree with the other biliary constituents is effected.

(b) **METABOLIC.** The typical "metabolic" calculus is the large single stone of almost pure cholesterol—the *cholesterol solitaire*. This type of stone, according to Aschoff, is formed quite independently of infection or injury of any sort and is due to the crystallization of cholesterol out of a bile surcharged with this material. The common mixed stones (cholesterol-pigment-calcium) are also composed predominantly of cholesterol and probably in many instances are metabolic rather than infective in origin. In certain conditions, e.g., pregnancy, in which gallstones are prone to develop, the blood cholesterol has been said to be higher than normal (hypercholesterolemia) and there is evidence of a disturbance in cholesterol metabolism. But as a matter of fact, hypercholesterolemia, according to Gardner, is not common in pregnancy, the normal proportions of free cholesterol to cholesterol esters (cholesterol combined with fatty acids), however, are altered, the former being increased, the latter reduced. Abnormalities in cholesterol metabolism leading to such changes are probably of more importance in the production of gallstones than a rise in the total blood cholesterol. It has already been mentioned that a high blood cholesterol does not cause an increase in the cholesterol of the bile. Also, in certain forms of renal disease in which hypercholesterolemia exists there is little evidence that the latter leads to the production of gallstones; in other forms of renal disease the incidence of gallstones is higher than usual, yet hypercholesterolemia does not occur.

It has been mentioned that increasing the cholesterol of the diet does not raise the cholesterol concentration of the bile, so there is no logical reason, as pointed out by Gardner and associates, for excluding cholesterol-rich materials from the diets of those subject to cholelithiasis. Indeed, a high fat diet, by

stimulating gall-bladder contractions and so preventing undue concentration and stasis of bile, may exert beneficial effect.

The ratio of cholesterol in bile to the bile salts is an important factor in the formation of gallstones. The cholesterol-bile acid ratio in normal bile is between 1:20 and 1:30. Since neither bile salts nor cholesterol are absorbed under normal circumstances from the gall-bladder this ratio holds for both liver and gall bladder bile. According to Andrews, deposition of cholesterol occurs when the ratio falls to 1:13. He believes that infection, when it is a factor, plays its part in gallstone formation not so much through increasing cholesterol production as through reducing the bile salt concentration, for he claims that bile salts are absorbed through the inflamed gall-bladder mucosa. Dolkart and associates attach more importance to the concentration of fatty acids in the bile than to that of the bile salts in preventing the precipitation of cholesterol.

"Pure" pigment stones (they contain calcium and cholesterol as well) also occur apart from infection. They are small, and dark and, though usually occurring in the gall-bladder, may be found in the bile passages. Their origin is not clear, but since they often occur in conditions associated with an abnormally high bilirubin excretion, e.g., acholuric jaundice, they may be the result of the precipitation of bilirubin from a bile which contains excessive amounts of the pigment.

(c) **STASIS OR SLOWING OF THE BILIARY FLOW** within the bile passages may be responsible for the formation of small stones of pigment-calcium in these situations. When there is complete stasis, due to mechanical obstruction, the fluid in the larger bile passages contains none of the important biliary constituents. The so-called "white bile" fills the ducts and in consequence the formation of calculi is not possible (p. 472). Stasis of bile in the gall-bladder is an important factor in the production of gallstones in this situation.

(d) **REACTION OF THE BILE.** Until the work of Drury, McMaster and Rous this factor had received comparatively little attention. These observers caused gallstones composed, in varying proportions, of calcium carbonate, pigment and cholesterol to be formed in the bile of dogs which had their gall-bladders removed and their common ducts drained into a system of tubing. Encrustations of biliary constituents as well as more or less discrete calculi formed upon the walls of the tubing. These occurred under sterile conditions and in the absence of stasis. The deposits are claimed to result from the alkalinity of the liver bile. Normal bile of the dog as it flows along the bile passages was shown by Okada to be definitely alkaline while that of the gall-bladder was acid. Rous and his associates found the liver bile of dogs to have a pH of 8.20 or more, while after its stay in the gall-bladder its reaction became decidedly acid—pH 5.18 to 6.00. Bile from the human gall-bladder, though less alkaline than liver bile, has rarely a pH below 7.0. One of the functions

of the normal gall-bladder (p. 473) therefore appears to be the acidification of the liver bile. So long as this occurs in the usual manner the calcium carbonate of the bile remains in solution. In an alkaline bile, such as is collected from the common duct in the absence of the gall-bladder the calcium carbonate is thrown down, and with it the pigment and cholesterol constituents, to be deposited upon the walls of the delivery tubing. These observations suggest therefore that in any condition which interferes with gall-bladder function, e.g., infection, injury, or intermittent stasis, the usual acidification of the liver bile will not occur; calcium carbonate will then undergo spontaneous precipitation, and serve as a center or centers upon which the other biliary constituents become deposited.

AN ENUMERATION OF HEPATIC FUNCTIONS

Besides its secretory and excretory functions dealt with in this section the liver plays an important rôle in many other physiological processes. For the reader's convenience a list of these with page references is given below.

- (a) Blood formation in the embryo (p. 77); hematitic principle in the adult (p. 65).
- (b) Fibrinogen production (p. 4).
- (c) Prothrombin production (p. 90).
- (d) Heparin production (p. 89).
- (e) Iron and copper storage (pp. 58, 59).
- (f) Blood volume regulation (pp. 286, 625).
- (g) Reticulo-endothelial activity (Kupffer cells) (p. 80).
- (h) Detoxication (p. 507).
- (i) Protein metabolism, deamination (p. 544), amino-acid synthesis (p. 545), urea (p. 546), and uric acid (p. 565), hippuric acid synthesis (pp. 392, 546).
- (j) Carbohydrate metabolism (p. 572).
- (k) Fat metabolism (p. 601).
- (l) Heat production (p. 628).
- (m) Formation of vitamin A from carotene (p. 636).

The hepatic circulation is dealt with in Chapter XXVIII.

LIVER FUNCTION TESTS

Several of the specific functions of the liver have been utilized as tests for the investigation of the functional capacity of the liver as a whole, i.e., as a means of detecting the presence of hepatic damage and, in some instances, of gauging the extent to which such damage has occurred. Some of these tests will be very briefly described, the accounts being confined in the main to the general principles upon which the tests are based.

A. TESTS BASED UPON THE EXCRETORY FUNCTIONS OF THE LIVER

The quantitative van den Bergh reaction has been described (p. 465). Since the excretion of bilirubin is

an essential hepatic function a determination of the quantity of circulating bilirubin is a valuable means of estimating the extent of liver damage associated with jaundice, provided the hyperbilirubinemia is not the result of biliary obstruction or of blood destruction. The galactose tolerance test as a means of distinguishing jaundice due to liver damage from that due to obstruction has been described (p. 465).

The estimation of the quantity of *urobilinogen* excreted in the urine (p. 460) has also been employed as a test of liver function, but increased blood destruction, as in pernicious anemia, quite apart from liver damage will cause urobilinogenuria. Under such circumstances urobilin estimations obviously will give no information concerning liver function. Also, infection of the biliary passages may increase the urobilinogen output out of all proportion to the reduction of liver function.

Other tests based upon the excretory function of the liver are the *bromsulphalein*, *bilirubin* and *rose-bengal* tests. In each of these tests the respective material is injected intravenously and the rate of excretion estimated from the quantity retained in the serum after the lapse of a specified time; the concentration of the material in the serum is determined colorimetrically. These three substances are excreted practically entirely by the liver and no significant amounts are taken up by the reticulo-endothelial cells. In normal persons practically no retention of bromsulphalein (5 mg. per kilogram of body weight injected) after 30 minutes, or of bilirubin (1 mg. per kilogram of body weight injected) is observed at the end of 4 hours. In the case of rose-bengal (10 cc. of 1 per cent solution injected without regard to subject's weight) 50 per cent or more disappears from the serum within 8 minutes after the injection. These tests, like the van den Berg test, will of course be of no value if obstruction of the bile ducts exists; obviously, whether damaged or not the liver cannot then excrete the injected substances. Colorimetric difficulties also render the dye tests inapplicable in the presence of hyperbilirubinemia from whatever cause. The bilirubin injection test is employed only in the absence of jaundice, for if the liver's power to excrete the endogenous bilirubin is depressed it is a foregone conclusion that it will show a corresponding incapacity to excrete the injected pigment. In the absence of jaundice, however, the bilirubin injection test is one of the most reliable means of estimating the degree of liver damage. Determination of the *serum phosphatase* level is one of the most sensitive tests of liver function. In hepatic damage the level is raised.

B. TESTS BASED UPON THE METABOLIC FUNCTIONS OF THE LIVER

(a) THE LEVULOSE (FRUCTOSE) TOLERANCE TEST. In this test the blood sugar curve is determined after the ingestion of from 40 to 50 grams of pure levulose dissolved in 250 cc. of water—the dose of sugar is varied according to the subject's weight. The test is

performed in the morning, that is, after a 12 hour fast. The blood sugar level is first determined before the ingestion of the sugar and every half hour for 2 hours thereafter. The liver converts levulose to glycogen, the greater quantity of sugar so converted the less pronounced will be the rise in the blood sugar. In the absence of hepatic disease the ingestion of 40 grams or so of the sugar causes a maximum rise of the blood sugar curve of 30 mg. per cent or less above the fasting level (when this is between 80 to 100 mg. per 100 cc.); the curve returns to within 15 mg. per cent of the fasting level within 2 hours. Definite hepatic injury is indicated by a rise in the blood sugar of over 30 mg. per cent when the fasting level is between 80 and 100 mg. per cent, and a rise of 35 mg. per cent, and of 40 mg. per cent when the fasting levels are from 70 to 80 and from 60 to 70 mg. per cent, respectively. Failure of the curve to return to within 15 mg. per cent of the fasting level after 2 hours, regardless of the height of the curve, is also definitely abnormal.

(b) **THE GALACTOSE TOLERANCE TEST** (see p. 465).

The levulose and galactose tolerance tests are of especial value in that they are applicable in the presence of jaundice.

(c) Tests based upon the function of the liver to deaminate the amino-acids with the production of

urea (p. 546) or upon its detoxicating function have also been devised. Though in the dog hippuric acid is synthesized only in the kidney, in the rabbit and in man this function is performed by the liver as well. In carrying out this test benzoic acid (5.9 grams) is given orally and the quantity of hippuric acid excreted in the urine at hourly intervals for four hours thereafter is determined. If the liver possesses some reserve function 3 to 3.5 grams are excreted within this time. The determination of the *prothrombin time* (p. 91) is also employed as a liver function test. In damage of the liver, the prothrombin time is prolonged.

It is to be remembered that the foregoing are purely functional tests and that a negative result does not necessarily indicate the absence of liver injury. On the contrary, liver disease may exist without its condition being revealed by any of these means. This is obvious from the observations of McMaster and Rous and Mann and his associates upon the reserve function of the liver. The first mentioned observers showed that in the dog 95 per cent of the excretory function could be abolished before jaundice appeared; Mann and his associates found that the liver tissue of the dog could be reduced by 80 per cent or more without a fall in urea production occurring.

CHAPTER XLII

THE GALL-BLADDER AND BILE DUCTS

Anatomy

The human gall-bladder has a capacity of about 50 c. Its wall is composed of a thin layer of muscle fibers and fibro-elastic tissue. It is lined by mucosa. The muscle fibers are sparse and loosely interlaced with one another and with the strands of fibro-elastic tissue. The mucosa is surmounted by a layer of columnar epithelium.

The *cystic duct* through which the bile enters and later leaves the viscus is tortuous, kinked or S-shaped and shows spiral folds of mucosa—the *valves of Heister*—within its lumen. The functions of these folds have not been clearly defined. They are not capable, apparently, of preventing either the entrance or egress of bile into or from the vesicle, though they offer a resistance of about 25 mm. of H₂O to the passage of fluid in either direction. They possibly serve a useful purpose in preventing kinking or twisting of the viscus, and retarding the inflow of bile. They are sometimes complete or may be absent. The cystic duct joins the hepatic duct at an acute angle to form the common bile duct.

The *common bile duct* passes very obliquely through the muscular wall of the duodenum and joins with the pancreatic duct to form the *ampulla of Vater* (fig. 198). The latter opens into the duodenum through an orifice situated at the summit of a small papilla about 3½ inches below the pylorus. The ampulla of Vater is surrounded near its outlet into the duodenum by a ring of muscle fibers—the *sphincter of Oddi*. The duodenal muscle in which the oblique intramural portion of the duct is embedded, exerts when contracted, a strong pressure upon the entire length of this section of the duct. The mucosa of the common duct is devoid of the usual mucous glands, but contains special branched tubular glands lined with tall columnar cells. These glands furnish a thin fluid which dilutes the bile.

The functions of the gall-bladder though important are not indispensable since it can be removed with impunity. After such an operation, however, the larger bile ducts undergo dilatation, which may in part compensate for the removal of the viscus. The gall-bladder is absent in some animals whose habits and digestive processes are not essentially different, apparently, from those of animals which possess one. It is absent in the horse, deer and rat but present in cattle, sheep, dogs, cats and mice. It is present in fish, amphibia and reptiles and birds, but is absent from mammals lower than these

CONTRACTIONS OF THE GALL-BLADDER AND COMMON BILE DUCT

The gall-bladder shows spontaneous *rhythmical contractions* which occur at the rate of from 2 to 6 per minute (in the dog), and also a *tonic contraction* which lasts for from 5 to 30 minutes or more. The rhythmical contractions (in the dog) are capable of producing a pressure change of from 250 to 300 mm. of water which is about the maximal pressure at which bile can be secreted by the liver (fig. 199). Rhythmical contractions of the common bile duct have also been demonstrated in animals.

THE FUNCTIONS OF THE GALL-BLADDER

THE CONCENTRATION AND STORAGE OF BILE—THE SECRETION OF MUCUS

Gall-bladder bile may be some ten times more concentrated in total solids than bile collected from the hepatic duct. Water and inorganic salts are absorbed through the lymphatics and blood vessels of the gall-bladder wall. The composition of the absorbed fluid is practically that of physiological saline. Bile pigments, bile salts and cholesterol are not absorbed to any appreciable degree under normal circumstances.

It is undecided whether cholesterol is excreted by the normal gall-bladder mucosa, though Elman and Taussig present evidence for such a process. In this connection it may be mentioned that a pronounced diffuse deposition of a cholesterol ester (35 to 60 per cent of the dry weight of the gall-bladder) in the connective tissue of the human gall-bladder wall is seen as a pathological condition. The tissue of the vesicle is stiff and greatly thickened as a result of its impregnation with lipid material. The disturbances leading to this condition, which is spoken of as *cholesterosis of the gall-bladder* or, from the appearance of the mucosa, as the "*strawberry gall-bladder*," are unknown; the existence of this condition cannot, however, be used as evidence for the secretion of cholesterol by the gall-bladder mucosa under physiological conditions. (See Elman and Graham.)

To the work of Hammarsten and more recently to that of Rous and McMaster we owe the greater part of our knowledge of the absorptive powers of the gall-bladder. By means of a cannula placed in the bile duct the latter observers collected the bile as it came from the liver and compared its composition with that in the gall-bladder. The bilirubin percentages of the respective fluids were used as a measure of the degree of concentration that had been effected in the bile during its stay in the gall-bladder. The bladder bile was found to be darker, thicker and more "syrupy" than the bile collected from the ducts. It contained from 3.1 to 10.8 times more bilirubin than the liver bile. Absorption occurred with remarkable rapidity in some instances. In one experiment about 50 cc. of bile

with a functionless gall-bladder. The "white bile" under these circumstances is furnished solely by the mucosa of the ducts. It contains no pigment, bile salts or cholesterol and bears almost no resemblance to bile. The secretion of the latter has been suppressed by the rise in pressure (to 300 mm. or so of water) within the duodenal system.

If the gall-bladder is healthy and left in communication with the obstructed system the sequence of events is entirely different. Biliary stasis then causes this *greenish bile* to collect in the ducts and bladder as result of the latter's concentrating activity, and of the mucinous material which it secretes. After a lapse of weeks the imprisoned bile develops an almost tar-like consistency. The functions of the ducts and of the bladder are therefore antagonistic, the former tending

D.W

FIG. 198

FIG. 199

FIG. 199. Examples of normal gall bladder contractions. Time marker, 1 second. (After Taylor and Wilson)

which entered the gall-bladder was reduced to less than 5 cc. in about 22 hours. In experiments involving the drainage of the gall-bladder through a cannula inserted into its fundus it has been shown that the mere passage of bile through the organ causes a nearly fivefold concentration. Inflammation of the gall-bladder reduces or abolishes its concentrating power.

The gall-bladder mucosa also adds to the viscosity of the bile by the *secretion* of a thick mucinous material. Little or none of this material is furnished by the bile ducts. Nor were the latter observed to have any concentrating power but were found, on the contrary, to dilute the bile with a thin watery fluid.

When the ducts were obstructed by ligation and the gall-bladder tied off, after some days a clear colorless fluid was found to have collected within the former. This fluid—the so-called "*white bile*"—is not uncommonly seen during an operation upon an obstructed bile duct associated

to dilute, the latter to concentrate the biliary fluid. The diluting effect is at first overbalanced by the concentrating action of the gall-bladder, and when the latter remains in communication with the duct system, the net result is marked thickening of the bile. There is, however, a tendency with time for the activity of the ducts to overcome that of the gall-bladder. The biliary constituents disappear and ultimately the contents of the system are entirely replaced by the thin simple secretion of the ducts and mucinous material from the bladder (hydrops). (Rous and McMaster)

These facts have a bearing upon the formation of gallstones (see also p. 468); since stasis and concentration of the bile are believed to be factors in this process it is evident that calculi are not likely to form as a result of obstruction of the *hepatic* ducts. The gall-bladder would in that case be situated beyond the obstructed system and could not exert its concentrating power.

Another type of "white bile" is sometimes produced. In dogs a clear colorless fluid is secreted by the liver cells when their true secretion is suppressed by some severe liver injury such as that induced by the administration of chloroform (Drury and Rous). "White

of this type is sometimes seen in the human subject as a result of hepatic disease.

Other functions of the gall-bladder subsidiary to its concentrating power are the *reduction in alkalinity* of the bile (p. 468) and the *equalization of pressure* within the biliary duct system. Without the ability to absorb fluid and reduce the bulk of the bile its power to equalize pressure would be negligible. It is to be remembered that the amount of bile secreted in 24 hours is one twenty times or so greater than could be contained in the gall-bladder. The loss of its function in equalizing the pressure within the duct system is probably a factor leading to the dilatation of the bile ducts, which so frequently follows removal of the gall-bladder (cholecystectomy). After this operation the flow of bile into the intestine is at first nearly continuous, but later the adaptation of the ducts permits intermittent discharge.

The importance of the gall-bladder in the control of pressure within the biliary ducts is apparent from the results of the experiments of Mann and Bollman. They found that after ligation of the common duct in dogs a rise in the bilirubin concentration of the blood did not occur until from 24 to 36 hours had elapsed, and jaundice did not appear for 2 days. If, on the other hand, the gall-bladder was removed at the time that the jaundice was fully developed within 24 hours due, presumably, to the rise in duct pressure, and the suppression of secretion of bile by the liver cells.

In dogs, cholecystectomy causes some impairment of liver function, as shown by the serum phosphatase test, (p. 469) for at least 70 days following the operation. In man, the excretion of urobilinogen is reduced for a short time after this operation.

THE FILLING AND EVACUATION OF THE GALL-BLADDER

As the bile as it leaves the liver flows into the biliary duct and thence into the common bile duct. During fasting its entrance into the duodenum is blocked by the sphincter of Oddi which remains tonically contracted. As the bile accumulates within the duct its pressure rises, reaching a height of from 50 to 70 mm. of water. This pressure forces its way along the cystic duct into the gall-bladder. During fasting therefore the gall-bladder becomes gradually distended with retained bile.

The nature of the force by which the gall-bladder is evacuated has been a question of some debate. The wall of the gall-bladder is so thin, and its muscle fibers so sparse, that it seemed unlikely that it could exert the pressure required to discharge its contents—especially since the gall-bladder is evacuated with considerable difficulty by manual compression. Intra-abdominal pressure, “milking” action exerted by the duodenal movements, and simple leaking into the duodenum as a result of relaxation of the sphincter of Oddi have been variously suggested as possible factors. Some have even contended that bile does not leave the gall-bladder by the cystic duct but is completely absorbed (Sweet). It has however, been proved quite definitely as a result of evidence derived from several modes of investigation that the contractions of the gall-bladder wall itself are responsible for the expulsion of its contents. The times of emptying of the gall-bladder are related to gastric digestion. During fasting it remains distended with bile though the sphincter guarding the common duct is relaxed, plainly indicating that the viscus is competent to retain the bile without the aid of the sphincter of Oddi. That changes in intra-abdominal pressure are not responsible for its emptying was shown by Mann and Higgins working with guinea-pigs. The gall-bladder of this species can be readily mobilized.

The abdomen was opened under local anesthesia, the gall-bladder exposed and drawn outside the abdominal wound, which was then sutured around the cystic duct. The vesicle was observed to contract and expel its contents in response to food placed in the duodenum. It was also shown that in fish, which of course have no diaphragm and in which, apparently, the intra-abdominal pressure remains constant, intermittent evacuations occurred. In dogs the influence of the sphincter was removed by suturing a catheter into the common duct; the abdomen was left open in order to minimize the effects of intra-abdominal pressure. The gall-bladder remained distended and expelled its contents only during the digestion of a meal.

When the walls of the gall-bladder contract, bile is discharged along the cystic and common ducts into the duodenum. The sphincter of Oddi normally can withstand a pressure of 100 to 120 mm. of water but the pressure developed by the contractions of the gall-bladder in dogs was shown by Mann and his associates to amount to over 250 mm. H₂O. It is probable moreover that relaxation of the sphincter occurs as part of a coordinated mechanism when the bladder wall

contracts, and that the passage of bile through the sphincter is not simply a matter of the latter "giving way" before the biliary pressure created by the gall-bladder contractions. The duodenal muscle surrounding the oblique intramural portion of the common bile duct (p. 471) is capable when contracted of offering a resistance of over 750 mm. of water. Since this is much higher than the pressure which contractions of the gall-bladder can exert, the flow of bile is completely blocked during contractions of the duodenal muscle but during the latter's relaxation the pressure is relieved (fig. 200). Therefore, during the evacuation of the gall-bladder and active duodenal movements, the bile may be observed to enter the duodenum in squirts. This is not due to the "milking" action of the peristaltic movements of the bowel but is simply the result of the alternate blockage and release of the duct, the bowel

gall-bladder when rendered opaque to the X by the administration of tetraiodophenolphth (p. 475) can also be seen to discharge its contents in response to a meal of fat. Its contractions during operations have also been observed frequently. The products of fat digestion, hydrochloric acid of a strength comparable to that in the chyme, or magnesium sulphate if placed in the duodenum, cause evacuation of the gall-bladder and relaxation of the sphincter of Oddi. Bile salts injected intravenously on the other hand, cause relaxation of the gall-bladder. Liquid petrolatum introduced into the duodenum is without effect.

The mechanisms controlling evacuation of the gall-bladder

(a) NERVOUS. It has been mentioned that relaxation of the sphincter of Oddi prob-

FIG. 200. This figure shows the relation between duodenal contractions and flow of bile (indicated in the near bottom of figure) from the common duct into the duodenum. (After Lueth.)

movements being incapable of causing any flow of bile when the gall-bladder is not contracting.

The most effective stimulus for the discharge of bile is fatty food, particularly egg-yolk, cream or olive oil. It appears that some degree of digestion of the fat must occur before evacuation results. The effect of fat upon the gall-bladder was shown definitely by Boyden. He found that during a period of fasting the gall-bladder in the cat was distended with bile, and its walls so stretched that they were reduced to about one-fifteenth of their thickness in the collapsed state. It emptied slowly after a meal, being collapsed, or nearly so, in from 1½ to 2 hours. The effect of meat upon the discharge of bile is much less than that of fat. Pure protein, such as egg white, and carbohydrate food is almost without effect. These findings have been amply confirmed by several observers. Whitaker and his associates, for example, observed changes in the contour of the gall-bladder after filling it with iodized oil and examining it radioscopically. The human

occurs as the gall-bladder contracts. An uncoordinated action of this nature points to a nervous mechanism. The latter may depend upon the intrinsic nervous plexuses in the walls of the biliary structures. The gall-bladder contractions initiated by the stimulus of a meal might be similar to short reflexes through the intrinsic plexuses of the stomach or duodenum and biliary tract. Nervous mechanisms are also indicated by the following observations. Electrical stimulation of the stomach and duodenum are sometimes followed by contractions of the gall-bladder. Contractions are occasionally induced by psychological influences, e.g., the smell or taste of food. The gall-bladder also responds to experimental excitation of the vagus or sympathetic nerves. Experiments attempting to demonstrate the precise actions of the extrinsic nerves upon the gall-bladder movements have, however, given conflicting evidence. Several observers have obtained weak motor effects from both vagus and sympathetic stimulation, a motor action

the latter is also indicated by the fact that adrenaline is excitatory.

The results of the experiments of Johnson and his associates, however, seem clear cut. Section of the right vagus nerve of the cat retarded emptying of the gall-bladder as a result, apparently, of the interruption of motor fibers to the gall-bladder and of inhibitory fibers to the sphincter of Oddi. The left vagus was found to carry motor fibers to the gall-bladder, but apparently does not contain inhibitory fibers to the sphincter. Reflex effects upon the movements of the gall-bladder may be initiated from other abdominal viscera. Stimulation of the duodenum, for example, causes inhibition of the movements of the gall-bladder. This reflex is abolished after section of the splanchnic nerves and excision of the celiac ganglion.

HORMONAL. Nevertheless, nervous mechanisms are not essential to gall-bladder activity; this is evident from the fact that the reaction to introduction of fat into the duodenum occurs without all nervous connections between the biliary and gastro-intestinal tracts, and between the brain and the central nervous system have been severed. That gall-bladder contractions can occur under such circumstances suggests, of course, a humoral or hormonal mechanism. Boyden found that the blood of an animal taken at the height of digestion, when injected into a fasting animal, causes the evacuation of bile; blood from a starved animal has no such effect.

Boyden obtained an acid extract from the mucosa of the upper part of the intestine which caused contraction of the gall-bladder when injected intravenously into animals. Acid itself is without effect when injected. Nor will fat or its derivatives excite contractions of the gall-bladder when administered intravenously. Acid and other substances which are excitatory when placed in the duodenum or fed therefore act apparently by stimulating the production or liberation of a hormone from the intestinal mucosa. The active principle is related to secretin but not identical with this hormone, for it does not cause pancreatic secretion, and secretin does not cause gall-bladder contractions. In crossed circulation experiments introduction of acid into the duodenum of one animal caused contractions of the gall-bladder in the other. Ivy and Oldberg named this principle "*cholecystokinine*." As little as 0.2 mg. of solid material prepared from a potent extract causes definite contractions of the gall-bladder. It is free from histamine and other

vasodilator substances. Its effect has been demonstrated upon man. The transfusion of blood from a human subject digesting egg yolk has been found to cause evacuation of the gall-bladder of the recipient. No effect was observed with blood from a fasting donor.

The actions of drugs upon the motility of the gall-bladder. Adrenaline, pitressin, histamine and mecholyl stimulate the smooth muscle of the gall-bladder, whereas morphine, ergotamine and atropine are inhibitory.

CHOLECYSTOGRAPHY

Graham and Cole showed in 1924 that if the chlorine radical of a dye such as tetrachlorophenolphthalein, which is excreted selectively by the liver, be replaced by iodine or bromine, the compound, after concentration in the gall-bladder, is opaque to the X-rays. Sodium tetra-iodophenolphthalein or the corresponding bromine compound (sodium tetra-bromphenolphthalein) is given intravenously or by mouth in a special coated capsule. After fasting for a period of about 14 hours a radiogram is taken. The normal gall-bladder at this time shows a well defined shadow. The gall-bladder is then stimulated to contract by means of a meal containing egg yolk and cream, and a second radiogram taken 5 hours later, when the normal organ should be found practically empty. The depth of the shadow after dye administration depends directly upon the concentrating power of the gall-bladder. For this reason a diseased gall-bladder may throw only a faint shadow or none at all.

Gallstones, which are relatively transparent to the X-rays, especially those of a high cholesterol content, show up against the gall-bladder shadow. Gallstones containing more than 0.5 per cent of calcium are visible without the aid of an opaque dye.

AFFECTIONS OF THE GALL-BLADDER AND BILE DUCTS

Among the common diseases of the gall-bladder are *inflammation* (*cholecystitis*), *gallstones* (*cholelithiasis*) and *new growths*. The factors involved in the formation of gallstones have been considered (p. 467).

In the absence of inflammation, stones in the gall-bladder give rise, as a rule, to no definite symptoms, but in their passage along the ducts severe pain—*biliary colic*—may be experienced as a result of the spasmodic contractions of the gall-bladder and consequent distension of the duct walls. Vomiting may occur as a reflex phenomenon. In the dog pain is produced when the gall-bladder is distended by a pressure of 540 mm. of water. This, of course, is a much higher pressure than the contractions of the gall-bladder can create. Pain is produced, however, by

distending the *ducts* with a pressure of 270 mm. of water—just about the maximal pressure which the gall-bladder contractions can produce. The cause of the expulsion of the stone from the gall-bladder is not altogether clear. Though contractions of the gall-bladder have been observed to cause movements of stones within its cavity, and even to force a stone into the cystic duct, gall-bladder contractions do not in the majority of instances offer satisfactory explanation for the expulsion of the stone. According to some, inflammation and distension of the gall-bladder are important factors leading to the passage of the stone into the cystic duct.

Biliary dyskinesia

It is now generally recognized that biliary colic may occur in the absence of stone, inflammation or of any anatomical abnormality, such as kinking of the cystic duct, which would hinder the expulsion of bile from gall-bladder. In such instances the colic has a functional origin, being due to the gall-bladder contracting

against a sphincter of Oddi in a state of spasm. Normally as already mentioned the sphincter relaxes and the gall-bladder contracts. In biliary dyskinesia nervous mechanisms upon which this reciprocal action depends are, apparently, disordered. It has also been claimed that a sphincter exists at the junction of cystic duct with the gall-bladder and that spasm of this ring of muscle during contraction of the gall-bladder may give rise to biliary colic.

Gall-bladder disease frequently gives rise to disturbances of other organs, particularly of the stomach. Anacidity or hypoacidity and increased motility of the pyloric part of the stomach are commonly encountered. Ivy and Fishback experimenting with dogs found that mild stimulation of the biliary tract inhibited gastric motility and lowered gastric tone. They suggest that in the human subject stimulation of this nature is conducive to gastric flatulence and belching. A sudden sharp distension of the bile duct caused pylorospasm and vomiting in their animals. According to some authorities dyspeptic symptoms in from 40 to 50 per cent of subjects are due to biliary tract disease. Cardiac irregularities may result through reflexes initiated from the gall-bladder or bile ducts (p. 209).

CHAPTER XLIII

THE MOVEMENTS OF THE ALIMENTARY CANAL

THE PHYSIOLOGICAL PROPERTIES OF SMOOTH (PLAIN, INVOLUNTARY OR NON- STRIATED) MUSCLE

The chief features of smooth muscle whereby it differs from skeletal muscle are: (a) sluggishness of contraction; (b) greater extensibility; (c) the exhibition of sustained contraction or tonus, even when isolated from the central nervous system; (d) the power of rhythmical contraction; (e) the possession of a double autonomic innervation (sympathetic and parasympathetic); (f) greater sensitivity to thermal and chemical influences and to certain types of mechanical stimulation, e.g., stretching, but a lower excitability to electrical stimulation; and (g) longer chronaxie.

As in the case of skeletal muscle and of heart muscle (p. 216), the force of the contraction of smooth muscle is dependent, within physiological limits, upon its initial length. Thus distension of the wall of the intestine as by the presence of gas or of fluids secreted as a result of a saline cathartic, causes powerful contractions of the bowel wall.

Tonus of smooth muscle is defined by Evans as the resistance which its substance offers to extension. The degree of tonus (T) may therefore be expressed thus;—

$$T = F/L$$

where F is the extending force and L the final length of the muscle subjected to the extending force.

The rhythmical contractions of smooth muscle are superimposed upon the tonus state which varies independently of the rhythmical contractions themselves and may be of high, of medium or of low degree. The processes underlying the production of tonus in smooth muscle are not clearly understood though it is possible that they are not fundamentally different from those responsible for the rhythmical contractions. It is probable that, as in skeletal muscle (p. 786), only a proportion of the fibers are contracting at one time during the tonus state. That is, at groups of fibers contract in rotation.

The chemical changes accompanying the contraction of smooth muscle are probably similar

to those occurring during the contraction of skeletal muscle (p. 612). Glycogen is broken down and lactic acid produced. In the absence of oxygen, lactic acid accumulates in the muscle contracting in nitrogen, and disappears upon the admission of oxygen.

The tonic contraction of smooth muscle is associated with a negligible expenditure of energy. The tonus mechanism is relatively insusceptible to fatigue; heat production and electrical changes are not detectable; and a rise or a fall in the degree of tonus is not accompanied by a corresponding change in oxygen consumption. Evans found, in fact, that a muscle, when in high tonus, used slightly less oxygen than when relaxed. The tonus of the smooth muscle of the gastro-intestinal tract is dependent mainly upon the intrinsic plexuses, though it is influenced through the extrinsic nerves as well. Tonus changes are also brought about through influences, e.g., changes in hydrogen ion concentration, acting directly upon the muscle fibers.

Postural tone

When a hollow viscus such as the stomach is gradually distended its walls become accommodated automatically to the greater volume, though the tone of the muscle at the new length is altered little from that existing before the distending force was applied. The pressure within the bladder or within the stomach (p. 487), for example, does not increase, or does so very temporarily when the contents of these viscera are increased in volume several fold. The tone of the muscular walls becomes adjusted to the "posture" of the viscus; the adjustment is analogous to the lengthening and shortening reactions of skeletal muscle (p. 827).

The inner mechanism whereby this "postural tone" is brought about is obscure. The great increase in capacity which can occur in a viscus such as the stomach is difficult to explain simply by assuming what the individual muscle fibers are increased in length. It has been suggested, therefore, that the muscle fibers, which are disposed in layers in the walls of the hollow viscera, slip over one another, the wall thus becoming

increased in area but reduced in thickness (Grützmacher).

MASTICATION

This act comprises movements of the lower jaw, lips, tongue and cheeks. Tearing of the food is effected mainly by the incisor teeth, grinding by the molars. The jaw movements consist of elevation and depression, protrusion and retraction, together with side to side motions; they are all controlled through the inferior maxillary division of the trigeminal nerve; they result in the conversion of the food into a fine state of division and its thorough moistening with saliva. The movements of the tongue and cheeks serve to pass fresh food material between the teeth, and to collect it after treatment by the teeth into a bolus suitable for swallowing.

THE ACT OF SWALLOWING (DEGLUTITION)

It has been customary since the time of Magendie to divide the act of swallowing into three stages.

The first stage is under voluntary control. The food which has been transformed into a soft mass by the act of mastication is brought into position upon the dorsum of the tongue, and by the action of the lingual muscles is rolled backwards towards the base of the tongue, where it lies just in front of the isthmus of the fauces. The *mylohyoid* muscle (p. 474) then contracts, pressing the tongue against the hard palate and carrying its base, which is also rotated through the arc of a circle having the hyoid bone as its center, sharply backwards. This movement which is effected with great speed propels the bolus with considerable force into the pharynx where it enters upon the second stage of its journey to the stomach. Other muscles, the *hyoglossi*, the *glossopalatini* and the *styloglossi* acting in conjunction with the *mylohyoids* assist in drawing the tongue backwards. As a result of the muscular movements, chiefly in the *mylohyoids*, a pressure of 20 cm. of water is developed in the posterior part of the mouth, pharynx and upper part of the esophagus. A negative pressure, however, exists in the anterior part of the mouth. A negative pressure also normally exists in the closed mouth at other times, which aids in holding the lower jaw in the elevated position.

The second stage is brief and is occupied in guiding the food through the pharynx and past the openings that lead from it. The muscular

movements during this stage are pure in nature. Having once passed through the isthmus of the fauces, the further progress of food is beyond voluntary control; though sometimes material can be returned to the mouth by a special effort of coughing or "clearing the throat." Upon the food entering the pharynx the constrictor muscles contract; the tongue is thus brought to bear upon the food forcing it into the esophagus, the *palatopharyngeus* and *pharyngeus* muscles at the same time draw the pharynx upwards over the bolus. There are, however, three other possible paths or directions along which the food may travel: (a) forward again into the mouth, (b) upwards through the naso-pharynx, and (c) downwards into the larynx. The return of food into the mouth is prevented by the contraction of those muscles which force the pharynx during the first stage. The

FIG. 201. Typical graphs of pressure in the pharynx during swallowing. Upper tracing (white), pressure in larynx recorded on a tambour. Lower tracing (black), record of pharyngeal pressure. (From after Anrep.)

of the tongue remains elevated and drawn upwards while the *pharyngeopalatini* and *glossopalatini* forming the faucial pillars contract, approximating the latter structures toward the midline, narrow the opening into the nasopharynx. A negative pressure amounting to 35 cm. of water is created in the pharynx and esophagus during this stage (fig. 201) thus aiding in the descent of the bolus.

The opening into the naso-pharynx is closed by the contraction of the *levator veli palatini* and *uvulae* muscles which pull the soft palate so that its posterior edge is approximated to the posterior pharyngeal wall. When this movement cannot be accomplished as in post-diphtheritic paralysis, bulbar palsy, etc., attempts to swallow liquids are followed by their regurgitation into the nasal cavities.

The entrance of food into the larynx is prevented by the contraction of the *epiglottis* muscle which raises the organ, bringing it under the shelter of the epiglottis and the tip of the tongue. The epiglottis itself, by

essential for the protection of the laryngeal opening, since when it is destroyed there is little fault in preventing the food from entering the air passages—the elevation of the larynx is the important safeguard; when it is fixed by base swallowing is difficult or impossible.

The epiglottis was at one time thought to serve as a sloping lid for the larynx over which the food passed in its passage downwards. This structure, however, stands erect and the food passes over its dorsal (posterior) not over its ventral surface. Coincidentally with the upward movement of the larynx the vocal cords are approximated. This is effected by the contraction of muscles attached to the arytenoid cartilages which are thereby drawn forwards from their usual positions against the posterior pharyngeal wall, and rotated medially. This manoeuvre has the two-fold effect of closing the glottis and causing the upper opening of the esophagus to gape. The food, being subjected to pressure by the contraction of the laryngeal constrictors, is forced along the path of least resistance.

At the short inspiration (inspiration of swallowing) which occurs at the very commencement of the first stage, and is followed by complete inhibition of expiration which persists until the end of the second stage.

The third stage involves the passage of the food into the esophagus. The food is seized by a peristaltic wave (p. 496) which, travelling along the esophagus, carries the material before it into the stomach. The cardiac sphincter guarding the lower end of the esophagus and which at other times is kept tonically closed relaxes upon the arrival of each of the bolus which is then swept into the stomach by the wave of constriction which follows.

Relationships. The food reaches the upper end of the esophagus in about 1 second after the commencement of the swallowing act. The rate of progress of the bolus along the human esophagus is not the same at all levels. The muscle in the upper or cervical portion of the tube, which is about 6 cm. long is of the striated type and consequently is capable of rapid contraction. Solid food traverses this section in about 1 second.¹ In the upper thoracic portion, which is approximately 10 cm. in length, the fibers are mixed, being striated, others unstriated, and the food takes 1.5–2.0 seconds to pass. In its lower thoracic portion the tube is composed entirely of unstriated muscle. Its length has not been determined precisely but the

esophagus of the dog is composed of striated muscle throughout.

Food takes about 3 seconds to pass through it. Solid or semi-solid food therefore takes between 6 and 7 seconds to pass from the mouth into the stomach.

When liquids are drunk the swallowing process is not quite the same. During the first stage the liquid is squirted forcibly into the pharynx and down the esophagus by the contraction of the mylohyoid and in less than a second reaches the lower end of the gullet which becomes relaxed throughout its entire length. That the fluid is not carried by a peristaltic wave but passes down the esophagus with great rapidity can be demonstrated by means of X-ray or by auscultation over the lower part of the esophagus when the sound of the fluid arriving here can be heard. On this account the accidental drinking of corrosive liquids tends to cause injury not equally throughout the length of the esophageal mucosa, as would occur if it were carried by a peristaltic wave, but more especially at certain points where the fluid strikes or collects, e.g. in the upper part of the esophagus and above the cardia. When a single mouthful of liquid is drunk the cardiac sphincter does not relax immediately upon the arrival of the fluid. This collects above the sphincter until a peristaltic wave, started in the upper part of the esophagus, arrives a few seconds later to relax the sphincter and carry the accumulated fluid through it. In other instances, the fluid is not shot down the full length of the tube but only as far as the lower part of the cervical segment or into the thoracic portion. The distance depends upon the degree of relaxation of the muscular walls and the force of the propulsive movement. When a series of mouthfuls of liquid are swallowed in rapid succession, as in drinking a glass of water, the esophagus usually relaxes throughout its length, and the fluid is projected to its lower end or even through a relaxed cardia directly into the stomach.

The first stage for the swallowing of liquids is not the same for all species. In the dog and most other mammals the squirting action is important. On this account these animals can drink in the head down position and force the fluid into the esophagus against gravity. This ability is dependent upon the contraction of the mylohyoid aided by the negative pressure in the pharynx and esophagus; removal of the pharyngeal constrictors does not interfere with it. In birds such as fowl, geese, etc. as was shown by Cannon and Moser, the passage of liquids as well as of solids is dependent upon peristalsis; there is no squirting action. These animals in consequence must raise the head in order to swallow liquids which are thus allowed to trickle by gravity into the esophagus. If the mylohyoid muscle is denervated in the dog liquids must be swallowed in a similar manner.

THE INNERVATION OF THE SWALLOWING REFLEX

Upon first thought, it might appear that the swallowing act could be initiated when desired, yet it is only the first stage that is under voluntary

control. If one wishes to swallow when the mouth is free of food or foreign material, a little saliva is passed backwards by the tongue and thus serves as a mechanical stimulus for the initiation of the second and third phases of the act which are purely reflex. If the mouth is kept perfectly free of saliva deglutition becomes impossible. The afferent fibers of the reflex are furnished by the *hypoglossal* nerve to the lingual muscles; the third division of the *trigeminal* nerve to the mylohyoid; the pharyngeal branches of the *glossopharyngeal* nerve and the pharyngeal and esophageal branches of the *vagus* (fibers of accessory nerve, see p. 862) to the muscles of the pharynx and esophagus.

That the carriage of food along the upper two-thirds or so of the gullet is dependent upon extrinsic nerves, and that the peristaltic contraction is not initiated or controlled by nerve plexuses within the wall of the tube, nor yet the result of a property inherent in the muscle itself was shown by the following experiment of Mosso. When the esophagus was cut across and a swallowing reflex then elicited by stimulating the pharynx, the peristaltic wave which followed "crossed" the gap and appeared in the lower segment. If the *vagus* fibers going to the esophagus are divided, paralysis with complete relaxation and dilatation of the upper two-thirds of the tube results; no peristaltic wave can be evoked, and food does not enter the stomach. On the other hand, the lower quarter or third, in an animal such as the cat of which this portion of the gullet is composed of unstriped muscle, continues to show active peristalsis and may for a time enter into a state of spasm. The cardiac sphincter (p. 481) passes into a state of tonic contraction. Stimulation of the *vagus* causes, as a rule, a strong contraction of the entire esophagus. The sympathetic causes, according to Knight, contraction of the upper and middle thirds and inhibition of the lower third of the tube.

The foregoing experimental results may be taken as evidence that peristalsis in the upper portions of the esophagus is carried out through a central reflex. In the lower esophagus, which in many animals and in man is composed of unstriped muscle, the initiation and transmission of the wave, like similar movements of the intestine (p. 496) devolves upon the intrinsic nervous mechanism. But also like the intestine this part of the tube can be influenced through the extrinsic nerves.

The afferent fibers of the reflex are furnished by the pharyngeal branches of the *trigeminal*, *glossopharyngeal*

nerve and the pharyngeal and superior laryngeal branches of the *vagus*, innervating the regions about the entrance to the pharynx. Usually a certain fairly well defined area of the fauces, the palate or of the pharyngeal wall—the location depending upon the particular animal species—can be stimulated which is more sensitive for the eliciting the reflex than any other. In man and cat, for instance, the most sensitive is the mucosa of the posterior pharynx supplied by the *glossopharyngeal*; in the dog it lies in the region of the tonsil and palate, the sensory innervation of the latter chiefly through the *trigeminal*. The *vagus* is also the most sensitive region in the larynx, though stimulation of other areas, such as the entrance to the larynx or the base of the tongue will also elicit the reflex. In man, the sensitive area has not been precisely determined, but the reflex is readily induced by stimulation of the posterior pharyngeal wall or of the base of the tongue. If the impulses from these areas be annulled by excision, swallowing is most difficult or even impossible. The central reflex cannot be initiated in the esophagus itself; a bolus placed in its middle third remains in position until the reflex is evoked by stimulating the pharyngeal wall.

Experimental stimulation of the central end of the superior laryngeal nerve will elicit the complete set of swallowing movements. The *glossopharyngeal* nerve contains afferent fibers which excite the reflex, others which inhibit it. A reflex started by stimulation, say, of the superior laryngeal may be cut short by stimulation of the central end of the *glossopharyngeal*. The tonic inhibitory effect of the *glossopharyngeal* may be shown by simply cutting the nerve, when the esophagus passes into a state of tonic contraction which persists for some time. The afferent *glossopharyngeal* fibers responsible for the inhibitory effect respond to a milder stimulus than those which excite the reflex. The *glossopharyngeal* also contains those fibers through which the reflex of respiration is effected reflexly during the act of swallowing the food through the pharynx. Stimulation of the central end of the nerve causes the breath to be immediately checked, either in inspiration or expiration according to the phase during which the stimulus is applied. The inhibitory effect of deglutition upon respiration may be demonstrated when the breath is held until the desire to breathe is imperative the distress is momentarily relieved by swallowing.

Deglutition centers

A large number of different nerves involved in the act of swallowing and the smooth manner in which the act, once initiated, is carried to completion indicate that the cranial nuclei are woven together by association fibers into a coordinated mechanism in which each nuclear part of the mechanism coming into action in accurately timed sequence and only, when the first of the series is excited. The central nervous tissue comprising this central mechanism is therefore diffuse and extends throughout the pons and medulla. A circumscribed area or center apparently does not govern this complicated mechanism. Marked this area to lie in the neighborhood of the nucleus ambiguus and above but independent of the respiratory center. Here, it is presumed, the afferent impulses are received and relayed to the motor nuclei. In progressive bulbar palsy the central mechanisms are very gravely affected as a result of the successive involvement of several nuclei.

PERISTALSIS IN THE ESOPHAGUS; HEART BURN; BELCHING

According to Alvarez, reverse wavelets or peristalsis commencing at the cardia and passing down along the esophagus to the pharynx is an uncommon occurrence in man; but reverse peristalsis is not seen unless some lesion exists. The reverse ripples in the esophagus are thought to be responsible for some symptoms of dyspepsia, e.g., the deposition of food upon the back of the tongue, bad breath, regurgitation of fluids into the mouth. Evidence of the existence of reverse movements in the esophagus was obtained by Kast who found lycopodium spores swallowed in a capsule recoverable from the mouth washings next morning in over 50 per cent of a series of human beings. The possibility of material from even the small bowel reaching the mouth is strongly suggested by the fact that lycopodium spores introduced into the colon by enema have been recovered some hours later from washings of the mouth.

"Heart Burn" is ascribed by Alvarez to the irritation of the mucosa of the upper part of the esophagus by acid fluid regurgitated from the stomach. Payne and Periton suggest that a tonic contraction of the esophagus set up by the acid stimulus is responsible for the sensation. Jones and others have produced it in normal persons by

distension of the lower third of the esophagus. The introduction of acid, cold water or gastric contents into this part of the esophagus also caused the burning sensation. Specimens of the wall of the tube was observed at the level in contact with the material and reversed peristalsis above. It is generally agreed that the sensation does not originate within the stomach itself.

BELCHING. The tendency, after a meal, for small amounts of gas to be expelled from the stomach into the esophagus and mouth is experienced by most normal persons. It is brought about, according to Alvarez, by reverse waves originating in the cardiac region of the stomach and ascending the esophagus. The repeated belching of gas is, however, abnormal. The gas in these instances is not, as a rule, produced by digestive or fermentative processes in the stomach, but is simply air which has been previously swallowed (aerophagy); it has the composition of atmospheric air. The greater part of the swallowed air does not enter the stomach but is held in the lower part of the esophagus until a sufficient volume has collected to give the subject a certain satisfaction when it is belched. The condition is seen in the nervous type of subject or in one who has some gastric discomfort; he resorts to the trick in an effort to gain relief. The intragastric pressure is not increased above the normal, apparently, in subjects who have the sensation of "gas on the stomach" and the pressure is not lowered after gas has been belched.

THE CARDIA

The muscular ring encircling the lower end of the esophagus is commonly known as the cardiac sphincter, though, as a matter of fact, in man the thickness of the muscle in this situation is scarcely greater than that in the rest of the tube. We have already seen that the cardia is held tonically contracted but relaxes upon the approach of a peristaltic wave or may even remain relaxed during a series of swallows, as in drinking (p. 475).

Experiments upon animals suggest that the cardia is supplied with both motor and inhibitory fibers from the vagus; stimulation of this nerve though followed in many cases by relaxation of the sphincter, at other times causes contraction. The character of the response, inhibitory or excitatory, depends, apparently, upon the degree of tone, high or low respectively, exhibited by the sphincter at the moment of stimulation. Observations upon cardiospasm (q.v.) suggest, however, that

in the human subject at any rate, *the chief influence exerted by the vagal fibers is inhibitory.*

The cardia is also innervated by the sympathetic, but there has also been some uncertainty as to whether this nerve exerts an inhibitory or an excitatory action. As in the case of the vagus both inhibitory and motor effects have been reported (Carlson) to result from its stimulation. However, *its predominant function in the human subject is probably excitatory.* The fact that section of the vagi causes the cardiac sphincter to enter into a state of spastic contraction indicates that in animals also, the sympathetic is mainly motor and the vagus inhibitory. Confirmatory evidence for this statement has been obtained recently by Knight in experiments upon cats. Vagal stimulation was followed in all cases by relaxation of the sphincter; sympathetic stimulation invariably caused contraction.

The cardia relaxes much more readily to pressure applied to its esophageal aspect than to pressure from within the stomach. In animals, a pressure of from 5 to 7 cm. of water on its upper surface is sufficient to cause relaxation, but a pressure of 25 cm. is required to be exerted from the stomach side. Alvarez found, however, that in the human subject the mere pressure of the stomach contents upon the cardia may cause it to relax. This fact was brought out by placing persons in the head down position. The tonicity varies in degree in different individuals, and in some, simply bending over forces the cardia, and causes a reflux of fluid into the pharynx or mouth, as a result, no doubt, of the compression of the abdomen, and the consequent elevation of intragastric pressure. It is to be recalled in this regard that the pressure in the esophagus is, like that within the rest of the thorax generally, subatmospheric. In individuals in which the tone of the cardia is lessened the "negative" pressure in the esophagus together with any increase of pressure in the abdomen, will encourage the regurgitation of fluid from the stomach.

The tone of the cardia is inhibited by mild stimulation of the gastric mucosa, and by sensory impulses arising in the mouth and pharynx. Its tone increases as digestion proceeds. The factor responsible for the increased tone does not appear to be the acidity of the gastric contents; the hypertonicity apparently is a part of the general increase in tone that occurs in the fundic portion of the stomach with the progress of digestion.

The tone of the sphincter may be increased reflexly by abnormally strong stimulation of the

stomach or of more remote regions of the alimentary tract. Afferent impulses arising from diseased gall-bladder and other abdominal organs have been held responsible for abnormally hypotonic states of the cardia.

CARDIOSPASM. Cardiospasm is the term applied to a condition in which the sphincter does not relax properly during deglutition; difficulty in swallowing (dysphagia) results, the subject complaining that food "sticks in his throat." X-ray examination frequently shows that the lower portion of the esophagus is dilated into a funnel-shaped or fusiform structure. The condition is usually one of incoordination between the muscle of the esophageal wall and the sphincter—*achalasia*—rather than one of actual spasm. The mode of its production is not known for certain. In some instances it may be reflex in nature and due to the irritation of afferent fibers in the stomach, gall-bladder or other abdominal viscus. In two cases reported by Rake, in which tissue was obtained for histological examination, degeneration of Auerbach's plexus (in which the vagal fibers end) was found. This observer considers the condition analogous to Hirschsprung's disease (p. 508) which is due to an imbalance between sympathetic and parasympathetic influences. These findings suggest that the normal action of the vagus upon this part of the alimentary tract of the human subject is to raise the tone of the esophageal wall and lower that of the cardia. Increased resistance at the cardia together with dilatation of the esophageal wall would therefore naturally result from disease of the vagal endings. Knight has reported treatment of cardiospasm and achalasia by gastric sympathectomy. But this operation which was designed to remove excitatory impulses is not, as a rule, permanently successful.

MECHANICAL FACTORS IN THE PHYSIOLOGY OF THE STOMACH

GENERAL CONSIDERATIONS. SHAPE, POSITION AND DIVISIONS OF THE STOMACH

The normal position of the empty human stomach is not horizontal, as used to be thought before the development of roentgenography. The greater part of the viscus is vertical or nearly vertical. In some subjects the stomach is shaped like the letter J, in others like a steer's horn and in others again like a reversed L. The majority of normal stomachs are J-shaped. In this type the pylorus lies at a higher level than the lowest part of the greater curvature and the body of the stomach is nearly vertical. In the steer-horn and reversed L types, on the other hand, the pylorus lies on a level with or below the most dependent part of the greater curvature. The body of the reversed

L-shaped stomach is also nearly vertical whereas that of the steer-horn type slants from above downwards and to the right (fig. 202). The hypotonic or atonic stomach tends to assume the J-shape; the hypertonic stomach is of the steer-horn type. The tone of the reversed L-shaped stomach is intermediate between the two.

The lowest point of the greater curvature reaches, usually, to about the level of the umbilicus, or to a line drawn between the highest points of the iliac crests. But even in quite healthy and apparently normal individuals it is often well

FIG. 202. Diagram showing the position and subdivisions of the stomach. A, B and C represent J, reversed L and steer horn types of stomach, respectively. D, stomach of the J-shaped type with the greater curvature lying well below the level of the umbilicus. Antrum is also known as the vestibule.

below the umbilicus in the standing position. A low position of the greater curvature has been looked upon in the past as pathological and has been believed to be the cause of various dyspeptic symptoms. X-ray examinations, however, have shown that in a large proportion of perfectly healthy persons the lower limit of the stomach may even be well down in the pelvis. But there is no "dropping" or ptosis of the viscus in the true sense, for the fundus remains in contact with the diaphragm. That is, the stomach is elongated but no downward displacement of the organ as a whole occurs. Most observers now believe that

the descent of the greater curvature is an unusual finding which, though sometimes associated with digestive disorders is not, as a rule, a cause of them, and may usually be disregarded. The stomach does not empty itself by gravity, but through the contraction of its muscular wall like any other part of the digestive tube, of which it is merely a dilated segment. It is not to be expected, therefore, that a lower position of a portion of a stomach with healthy muscle would necessarily affect its emptying any more than the evacuation of a loop of intestine would be influenced by the position which it occupied in relation to the rest of the intestinal canal. The pylorus lies in or a few centimeters to the right or left of the mid-line. When the stomach fills, the pylorus moves to the right.

FIG. 203. Upper series, X-ray appearance of stomach at 200 second intervals following the ingestion of a liquid meal. Lower series, appearance of stomach at 5, 5, 5 and 10 minute intervals, respectively, after the ingestion of a solid meal. (After Wilson, Dickson and Singleton.)

The wall of the stomach is composed of a serous coat and three layers of muscle fibers—longitudinal, circular and oblique, from without inwards. The mucous membrane is thrown into numerous ridges or folds called *rugae*. These are particularly well marked when the stomach is empty but tend to become flattened out as the organ becomes distended. There is a well marked *muscularis mucosae*. The capacity of the stomach is from 1 to 1½ quarts.

The portion of the stomach lying above an imaginary horizontal plane passing through the cardiac orifice is called the *fundus* (fig. 202). It is filled with entrapped gas. The more or less vertical portion of the organ below the fundus is called the *body*. The succeeding portion, represented by the hook of the J in the case of the J-shaped stomach, is known as the *pyloric part* (pars pylorica) and consists of a proximal chamber the *antrum* or *pyloric vestibule* and the *pyloric canal* through which the stomach communicates with the duodenum. The notch at the lower end of the lesser curvature formed by

the bending of the pyloric part upon the body, is known as the *incisura angularis*. The pyloric canal is a narrow passage about 3 cm. long around which the circular coat of the stomach is thickened to form the *pyloric sphincter*. The thickening of the muscle causes a projection of the mucosa which is responsible for the narrowing of the digestive tube at this point and for the slight circular depression on its outer surface. The musculature of the stomach is almost completely separated from that of the duodenum by a ring of connective tissue.

THE MOTOR ACTIVITIES OF THE STOMACH

When the stomach is empty its cavity below the upper part of the fundus, which as mentioned above is inflated with gas, is completely obliterated by the apposition of the gastric walls. Food, after passing through the cardia, collects just above the obliterated portion; apparently simply of its own weight it gradually separates the gastric walls, and passes downwards along the lesser curvature into the body and pyloric part of the organ (fig. 203). This passage-way is sometimes referred to as the *magenstrasse*. The fundus and usually the remainder of the stomach above about the middle of the body shows no peristaltic activity. The muscle of this part of the organ is the seat of a weak tonic contraction which is immediately inhibited by the entrance of food into the stomach—*receptive relaxation*, or even by the presence of food in the esophagus (see also p. 488). The pyloric part, on the other hand, constitutes a chamber wherein the food is macerated, fragmented, and thoroughly mixed. Peristaltic waves commencing near the middle of the body of the stomach sweep downwards through the pyloric vestibule. They are shallow and ill-defined at their commencement but become stronger as they descend. They also increase in strength as digestion proceeds and, when this is at its height, bite deeply into the gastric walls. Cole has studied the waves in the human stomach by means of serial roentgenography and cinematographic projection. He describes the peristaltic movement as a band of constriction which becomes well marked in the region of the *incisura angularis* and ends a centimeter or two above the commencement of the pyloric canal. The gastric wave travels more rapidly over the greater curvature than over the shorter distance of the lesser curvature, and according to Cole the constriction on the lesser curvature upon reaching the *incisura angularis* "marks time," while that on the greater curvature

continues on through the antrum. The wave thus executes a sort of wheeling movement.²

Two or more peristaltic waves may be seen at a moment travelling through the lower part of the body and pyloric region; for this reason the X-ray appearance of the actively motile stomach is irregularly convoluted. The waves in their downward journey show rhythmic variations in depth. They might be described as waxing and waning. At one instant they deeply indent the gastric wall and the segments between the annular constrictions are also reduced in diameter. There appears to be a general increase in tone of the gastric wall, the capacity of the entire pyloric region being reduced. At the next instant there is a general reduction in tone, the waves are less intense, the convolutions of the stomach outline less pronounced, and the capacity of the pyloric region increased.

Cole compares these rhythmical alterations in the organ's shape to the cardiac cycle, and speaks of a *gastric cycle*. From the moment that a particular stomach shape appears to the instant when that form again comes into view constitutes a complete cycle of gastric movements. *Gastric systole* is that phase marked by deep indentations made by the constricting rings, and reduction in gastric capacity. *Gastric diastole* is the period during which the contractions having become momentarily weakened show less tendency to deform the gastric outline. (Figure 204 shows a series of roentgenograms representing a gastric cycle. Systole, I to IV inclusive, and diastole, VIII to X, may be readily distinguished). A complete cycle occupies about 15 seconds. Systole occupies $\frac{7}{10}$ of the cycle; diastole

Gastric motility shows great individual variation; in some types of stomach the wave travels very rapidly, completing its journey in from 5 to 15 seconds. In others the wave takes 30 seconds or so to pass from its origin to the pylorus. The slow waves are the more common.

Apart from these individual differences, the motor activity of the stomach is influenced by the chemical characters and bulk of the meal. Fat and its derivatives, fatty acids and soaps, for example, inhibit the movements, reduce the depth of the peristaltic waves, and lower gastric tone. Fat exerts this effect while in the

² Cole maintains that the peristaltic movement is a function of the muscularis mucosa and not of the regular muscular coats. Some support for this view has been furnished by Gordon and Singleton who fastened steel beads to the outer surfaces of the curvatures of the stomach and studied the gastric movements by roentgenography, a barium meal having first been given. Waves were observed at times which did not disturb the alignment of the beads. They conclude that the stomach wall exhibits two types of peristaltic movement, one a vigorous peristalsis, which involves all coats of the stomach and another, a weaker movement, involving the mucosa and muscularis mucosa only.

stomach and also after reaching the duodenum. Ivy and his associates have obtained evidence that the inhibitory effect of fat is mediated through a chalone (see enterogastrone, p. 436). Fat introduced into the stomach by a stomach tube inhibited the movements of a transplanted gastric pouch after a latent period of 5 minutes.

Some of the products of protein digestion in the intestine (e.g., the monoamino-monocarboxylic acids) and hydrochloric acid inhibit gastric tone and peristalsis. This action which is referred to as the *enterogastric reflex* is brought about through the vagus. Sugars in high concentration

a meal has its origin in one or other of such nervous factors as those just mentioned. When food is taken while one is fatigued, anxious, agitated or hurried, disturbances of the normal motor mechanisms of the stomach give rise to unpleasant gastric sensations. The precise manner in which these are set up is not clear, but it is not unlikely that, in some instances at least, with the inhibition of the normal descending waves of peristalsis, reverse waves arise which lead to heartburn, belching and a feeling of discomfort (p. 481). But whatever the mechanism, the relation of psychic factors to gastric symptoms is clearly

FIG. 204. Serial X-ray photographs of human stomach taken at 2 second intervals during digestion to illustrate a gastric cycle. (From Cole.)

also inhibit gastric movements; this effect is probably induced through the medium of enterogastrone rather than by a reflex mechanism.

In the intact normal stomach distension of the gastric walls acts as a stimulus though extreme distension is inhibitory. Nervousness and anxiety tend to increase peristalsis while certain other emotional states—apprehension, fear, mental strain, shock or depression—tend, as a rule, to inhibit the movements and to reduce gastric tone. Pain and physical fatigue act similarly. Exercise unless very moderate tends to inhibit gastric motility.

It is believed that in many instances the discomfort or distress which follows shortly after

evident. This so-called nervous dyspepsia is, to quote Alvarez, "the disease of the mother who prepares the meal and then wrangles with children or husband at the table; it is the disease of business men and women who gulp down some food at a counter and rush back to work; and it is the disease of the president of a luncheon club, or of the traveling salesman who gives 'pep talks' at luncheons and dinners."

Among chemicals which influence gastric motility the following may be mentioned. Alcohol, lactic acid, coffee, sodium bicarbonate in therapeutic doses, histamine, insulin and choline increase peristalsis; smoking, atropine, vitamin B₁ deficiency (p. 642) infectious fevers

and anoxia depress it. Morphine increases the tone and amplitude of the contractions of the pyloric sphincter; its effect upon the antrum is variable.

THE EMPTYING OF THE STOMACH

After an ordinary mixed meal the normal human stomach empties in from 3 to 4½ hours. A meal consisting mainly of carbohydrate leaves more rapidly than one containing much meat, and this more rapidly than one containing fat. A test meal is evacuated in 2 hours on the average. Fluids and semi-fluids commence to leave the stomach almost immediately after being swallowed (see table 35).

by chloroform and ether and the least by nitrous oxide and cyclopropane.

The rapidity with which raw egg white or whey leaves the stomach, as well as the normal sometimes shortened emptying time in gastric anacidity (p. 740) had always offered obstacles which the acid theory of pyloric control found difficult to surmount. McClure, Reynolds and Schwartz have shown clearly that no important relationship exists between the emptying time and gastric or duodenal acidity. The maintenance of a constant acidity in the duodenum did not prevent pyloric opening. On the other hand, when the duodenum was kept neutral or alkaline by means of fluid introduced through a duodenal

TABLE 35

The theory propounded by Cannon, that the pylorus is controlled by the acidities of the gastric and duodenal contents—high gastric acidity causing opening and high duodenal acidity closure—is held no longer. A stimulus of practically any sort arising in the duodenum can reflexly increase the tone of the pyloric sphincter and effect its closure, a high acidity can serve as such a stimulus, but it has no specific effect in this regard. A high degree of alkalinity in the duodenum also inhibits gastric motility and delays evacuation. The emptying time of the stomach is actually shortened by reducing the gastric acidity, as by the ingestion of sodium bicarbonate or of disodium phosphate (Van Liere and Sleeth). Bile salts reduce the emptying time of the human stomach. The emptying time is prolonged by general anesthetics, the greatest increase being caused

by tube, rhythmical opening and closure of sphincter occurred in the usual way. Nor was Baird, Campbell and Hern able to obtain evidence for the acid theory of pyloric control from experiments on human subject. The emptying time of the stomach showed no dependence upon reaction of the gastric or duodenal contents. Essentially similar results have been obtained by McCann and several other investigators.

The opinion is now widely held that the pylorus is patent for the greater part of the time and that the evacuation of the stomach is definitely related to the peristaltic activity of the antrum. Wheelon and Thomas obtained simultaneous records in animals by means of balloons placed respectively, in the pyloric antrum and the pyloric canal, which showed that as the constricting wave traverses the antrum the sphincter becomes

relaxed and the chyme is swept before the wave into the duodenum. The pylorus then closes for a moment, relaxing again and remaining open until the next wave of constriction arrives from the antrum. Graphic records obtained by means of balloons placed in the antrum combined with X-ray examination also show that the emissions of chyme through the sphincter are coincident with the passage of waves over the former region (Carlson and associates), and Baird, Campbell and Hern found that in the human subject fluids shortly after being drunk issued from a tube placed in the duodenum just beyond the pylorus not continuously, but in jets. According to Cole's description, the pylorus closes at the end of gastric systole (p. 484), remains closed during the commencement of diastole, but then relaxes and remains relaxed during the greater part (nine-tenths) of the gastric cycle. The importance of the pylorus (the keeper of the gate) in controlling gastric evacuation has, therefore, been greatly exaggerated. X-ray examinations of the stomachs of patients in whom the pylorus has been excised, show emptying times which do not differ significantly from the normal (Singleton).

It is apparent from the foregoing discussion that factors which increase or diminish *gastric tone* and the *force of the antral contractions*, will shorten or lengthen, respectively, the evacuation time. The immediate factor which determines the rate of gastric evacuation appears to be the pressure gradient between the antrum and the duodenal bulb. Fat, for example, inhibits gastric motility and so delays the emptying time.

The degree to which the gastric contents have been reduced to *fluid or semi-fluid consistency* appears also to be an important factor determining the rate of emptying of the stomach. As already mentioned, water drunk by the human subject passes through the pylorus in squirts almost immediately after having been drunk. In the early stages of digestion, when the food contains pieces of solid material, the tone of the pylorus is higher than in the later stages, when the gastric contents are in a semi-fluid state. Raw egg white and fluid milk also leave more rapidly than coagulated egg-albumin or clotted milk. The shorter emptying time of carbohydrate food as compared with protein is due probably to the greater readiness with which the former is reduced to a semi-fluid state. The details of the mechanism whereby the consistency of the food and the emptying rate are correlated are not clear, unless, as has been suggested, solid particles act as mechanical

stimuli which cause pyloric closure and possibly set up retrograde waves in the vestibule. Cannon fed pellets of a bismuth salt to an animal and, observing the gastric movements by means of the X-ray, saw the opaque particles carried up to the pylorus by peristaltic waves. They were not, however, allowed to pass into the duodenum but were returned to the vestibule. They were retained in the stomach after the rest of the gastric contents had been discharged. Retrograde waves in the vestibule have also been observed by Kleine and others when solid materials such as undigested meat came into contact with the mucosa in the region of the pylorus.

The observations of Apperly and several other investigators indicate that the *osmotic pressure* of the gastric contents is another factor influencing the emptying time of the stomach. Macleod and associates found that hypertonic glucose solutions when fed to rats were reduced to isotonicity before evacuation occurred, and McSwiney and Spurrell observed that hypertonic meals delayed gastric evacuation, proportionately to their hypertonicity.

Finally, *the state of the upper part of the duodenum* (p. 490)—its fullness or emptiness, which thus alters the pressure gradient between the antrum and the duodenal bulb—has also a pronounced effect upon the state of the pyloric sphincter and the emptying time of the stomach. It has been mentioned on page 485 that certain digestive products in the duodenum cause gastric inhibition through the enterogastric reflex or through the liberation of enterogastrone.

The main factors, therefore, which influence the emptying time of the stomach are: (a) the motility of the stomach itself, (b) the consistency of the gastric contents, (c) the osmotic pressure of the gastric contents, and (d) the quantity of material in the duodenum. It should be remembered that the pressure in the antrum must exceed that in the duodenum in order for the stomach to empty. Gastric evacuation is also influenced to some extent by the position of the body, emptying being more rapid when the subject is lying upon his right side than when standing or recumbent upon his left side.

INTRAGASTRIC PRESSURES

The pressure within the human stomach varies in the standing or sitting position from 6 to 10 cm. H₂O. In certain other positions, as shown by Wilson and Irving, e.g., stooping or lying on the right side, the pressure is frequently subatmospheric (−1 to −5 cm. H₂O). The

pressure in the fundus is considerably lower than that in the pyloric part. This indicates that the tonic contraction of the fundic walls does not serve to press the food towards the pylorus, as has sometimes been supposed. In the dog, intragastric pressures up to 90 cm. of water have been observed. The pressure is usually higher in the antrum than in the duodenal bulb. The intragastric pressure varies with the intra-abdominal pressure and with the respiratory movements.

As already mentioned, the entrance of material into the stomach causes a reduction in the tone of the gastric musculature, and an increase in the capacity of the stomach for the accommodation of the ingested food or drink (see postural tone, p. 477). If, for example, a large quantity of water be drunk the upper surface of the fluid in the stomach as shown by X-ray rises very slowly and, after reaching a point about the middle of the body, remains practically stationary at this level; though an additional quantity of fluid be drunk, little change in the level of the fluid occurs. Ordinarily, the intragastric pressure shows no increase after the ingestion of a meal; and even after a liter or so of water has been swallowed no rise in pressure, or only a very transitory one, can be detected. Conversely when fluid is withdrawn from the stomach the gastric capacity becomes automatically reduced and the intragastric pressure remains practically unaltered. The adjustment of the gastric capacity to the volume of the food appears to be dependent in part at any rate upon a central reflex. According to Kelling it is abolished by deep anesthesia. Adaptation is shown, however, to some extent even by the excised stomach. The increase in gastric capacity is accompanied by reflex relaxation of the abdominal muscles. If, on the other hand, an amount of fluid which when taken into the dog's stomach causes no change in intragastric pressure is injected into the peritoneal cavity, relaxation of the abdominal muscles does not occur and the intra-abdominal pressure rises in proportion to the volume of the fluid which has been introduced. The intragastric pressure rises, of course, to a corresponding degree. The discomfort and sensation of fullness after a meal eaten hastily or under conditions of nervous strain are attributable in many instances to the inability of the gastric wall and abdominal muscle to become accommodated rapidly enough to the increased volume of the stomach contents.

THE INNERVATION OF THE GASTRIC MOVEMENTS

The stomach contains intrinsic plexuses (of Auerbach and Meissner) similar to those in the intestine (p. 501). Its extrinsic innervation is through both the right and left vagus nerves and the sympathetic (fig. 205). The fibers of the vagus end around cells in Auerbach's plexus.¹

¹ Both vagus nerves enter into the formation of the esophageal plexus. From the latter, two trunks, each of which contains fibers from the right and the left vagus, emerge. The anterior vagal trunk supplies the anterior surface of the stomach and the posterior trunk

The postganglionic fibers of the sympathetic (cell stations in celiac ganglion) end by arborizations around the muscle cells. The effects of the experimental stimulation of either of these nerves cannot always be predicted. Vagal stimulation may cause either augmentation or inhibition of gastric motility. Inconstant effects are also caused by sympathetic stimulation. The result obtained depends upon several conditions, e.g., the frequency and strength of stimulus, the level of the tone of the muscle at the time and the activity of the peristaltic movements. Generally speaking, when the tone of the gastric muscle is high, inhibitory effects are produced by vagal stimulation, whereas in states of low tonus a motor effect is obtained. McCrae and McSwiney and Stopford found that when the *rhythmical movements* were present in the antrum, vagal stimulation caused inhibition but, if the movements were absent, vagal stimulation initiated them. Similarly in the case of the sympathetic, when hypotonus or hypertonus pre-exists, stimulation causes augmentation or inhibition, respectively, of gastric motility. Inhibition of the rhythmical movements of the antrum most frequently follows sympathetic stimulation but again the result is not predictable; increased activity may result. The sympathetic is generally considered to be inhibitory to the pyloric sphincter and the vagus excitatory, but an opposite effect may be obtained from either nerve, the tonus level at the time appearing to be a determining factor. Though variability of response is quite evidently a characteristic of the gastric nerves, their functions can be summarized in the statement that *the vagus is predominantly motor, the sympathetic predominantly inhibitory*. Thomas and Crider observed that, in dogs, vigorous gastric peristalsis ceased immediately upon sectioning the vagus nerves; the stomach remained quiescent for hours. But when the sympathetic nerves are sectioned, as well, although there is inhibition of peristalsis for a time, motility soon returns. This suggests that a tonic inhibitory influence, exerted by the sympathetic innervation is responsible for the abolition of gastric motility when the vagi alone are sectioned. In man, decrease in tone and in the motility of the stomach and reduction in the tone of the pyloric sphincter

the posterior surface. Each aspect of the stomach thus receives fibers from both vagus nerves. The pylorus and first part of the duodenum receive a special branch which arises from the anterior trunk. This branch also sends twigs to the liver. The posterior trunk supplies a large branch to the celiac plexus. (See McCrae)

have been reported to result from section of the gastric vagi. On the other hand, section of the

sympathetic innervation has been found to increase the motility of the human stomach. The innervation of the cardia is discussed on page 481.

After section of both sets of extrinsic nerves to the stomach, motility is abolished but returns after a time, the movements then being governed by the intrinsic nervous mechanisms. The evidence for the liberation of acetylcholine by vagal stimulation is given on page 948. The gastric vagi also contain afferent fibers. Section of one vagus and stimulation of its central end is followed by movements of the stomach.

Evidence for a diencephalic center for gastric movements has been obtained by Beattie and Sheehan. Stimulation of the hypothalamus in the region of the tuber cinereum resulted in contractions of the stomach; the effect was abolished by section of the vagi. Stimulation of the posterior hypothalamic region, on the other hand, inhibited all gastric movements. Sheehan in a later communication reports that cooling or faradic stimulation of the frontal or premotor area of the cortex in the monkey inhibited the movements of the stomach which had been contracting actively. Contractions could not be initiated in a resting stomach by stimulation of the cortex.

ACUTE DILATATION OF THE STOMACH

In this grave though comparatively rare condition the stomach becomes greatly, sometimes enormously, distended; its cavity contains large quantities of fluid and gas which may stretch its walls to paper thinness. The accumulated fluid of course represents a corresponding loss of water and chloride from the body's stores. Reduction in blood chloride, alkalosis and dehydration result (p. 511); tetany may occur (p. 701). There is profound prostration; collapse ending in death is not uncommon. The condition, in the majority of instances, occurs as a sequence of an abdominal or pelvic operation but it occasionally follows a blow upon the abdomen, some severe injury, childbirth, a drinking bout or overeating.

The condition is apparently of reflex origin, the initial and essential factor being the loss of gastric tone. The stomach then becomes distended by the accumulation of its own secretions which it is unable to expel, as well as by the regurgitation of fluids from the duodenum. Even the normal stomach and also probably the upper part of the duodenum cannot absorb the fluids which they secrete, so if the gastric secretions do not leave the stomach they simply collect and gradually increase in volume. Hypersecretion, apparently, is not a factor in the early stages at any rate. Later, however, the distension of the gastric walls probably acts as a stimulus to secretion (p. 433). In some instances, swallowed air and intestinal gases play a part in ballooning the relaxed organ. According to Dragstedt when the dilatation reaches a certain degree an added factor comes into

play; the enlarged stomach by its pressure obstructs the third part of the duodenum.

THE DUODENAL BULB OR CAP

The first two inches of the duodenum are referred to as the duodenal bulb or cap; this region is of special interest since it is the site of duodenal ulcer (p. 444). Functionally, the duodenal bulb is considered by most observers as part of the stomach. It is somewhat triangular in outline with its base surmounting the pylorus and is directed backwards, upwards and to the right (fig. 202). Its glands (Brunner's) secrete an alkaline fluid. Its junction with the duodenum proper is marked by a slight thickening of the circular muscle fibers which are believed by some to exert a sphincter-like action. During the period of gastric evacuation the bulb becomes filled with chyme. From time to time a peristaltic wave sweeps over it from base to apex, carrying its contents into the next section of the duodenum. The chyme is also conveyed into the duodenum proper in a passive manner, that is, by the simple overflowing of the bulb. Occasionally an antiperistaltic wave arises in the duodenum below the cap, continues upwards to the pylorus and appears in the pyloric vestibule.

Related movements of the pyloric vestibule, pyloric sphincter and the duodenum below the bulb

Wheelon and Thomas placed recording instruments in the pyloric antrum, pyloric canal, and duodenum distal to the cap, and obtained simultaneous tracings of the contractions in these three situations. The movements of the antrum and sphincter were found to be related with those of the duodenum. During the contraction of the antrum the duodenum is relaxed, but about one minute after the commencement of the relaxation of the vestibule the duodenum commences to contract. That is, relaxations of the vestibule roughly coincide with contractions of the duodenum and contractions of the antrum with relaxations of the duodenum (receptive relaxation of the duodenum). Contractions of the sphincter were found to occur rhythmically from 3 to 5 times per minute, each contraction commencing while the duodenum was relaxed. The contraction of the duodenum commenced $2\frac{1}{2}$ seconds later but the contractions in the two situations reached their maximal heights at about the same time. These movements of stomach and duodenum are correlated apparently through the intrinsic plexuses in the gastrointestinal wall. A connective tissue barrier exists between the muscle of the stomach and duodenum which must prevent the continuous spread of the wave independently of a nervous mechanism of some sort.

Movements initiated in the duodenum have been

shown, on the other hand, to influence the activities of the sphincter. When the duodenal mucosa was stimulated an ordinary peristaltic wave appeared which travelled down the bowel in the usual way (p. 496), but a firm contraction of the sphincter also occurred, followed by a prolonged period of relaxation. A series of such stimuli produced a continuous contraction of the pyloric sphincter. Activity of the duodenum has been shown by several observers to have the effect of increasing the tone of the sphincter. The state of the duodenum in this way affects indirectly the emptying of the stomach, and the filling and emptying of the cap. When the duodenum is filled with chyme active movements are set up in its wall which have the two-fold effect of withdrawing material from the cap and causing reflex closure of the sphincter. When the duodenum becomes empty its activity subsides, the pylorus relaxes more fully and the emptying of the stomach is hastened. This effect of a full duodenum upon the emptying time of the stomach is shown by the fact that a meal taken after a period of fasting is discharged much more rapidly than if the duodenum is already replete with chyme; gastric evacuation is then delayed. Distension of the bowel by a balloon or its irritation by chemical or mechanical means increases pyloric tone. It has been shown repeatedly on the other hand that if the chyme as it issues from the pylorus be allowed to escape through a fistulous opening instead of being permitted to fill the duodenum, the stomach empties with greater speed. It has been found by Thomas, Crider and Mogan that a reflex effect of even greater importance than that upon the sphincter is exerted from the duodenum upon gastric peristalsis. Substances introduced into the duodenum markedly reduced the force of the peristaltic waves in the antrum, whereas draining the duodenum increased gastric motility and hastened gastric evacuation.

Antiperistalsis in the second and third parts of the duodenum

Antiperistalsis is a normal occurrence in the duodenum below the cap, the reverse waves can be seen during X-ray examination of the human subject passing orally and conveying material to a higher level of the duodenum, into the cap or through the pylorus into the stomach.

VOMITING OR EMESIS

The mechanism of vomiting involves the co-ordinated actions of the muscles of the stomach, esophagus, and abdominal wall. The act may also be associated with antiperistaltic movements in the intestine. The muscular mechanisms are governed by a center in the medulla, which discharges impulses along numerous efferent nerves, and may be influenced by afferent impulses arising in the stomach, in other viscera or in practically any region of the body. Or, the center

may be excited by substances conveyed in the blood stream (p. 493).

THE VOMITING MOVEMENTS

Cannon has given a graphic account of the act of vomiting in the cat. The movements were observed by means of radiography after a bismuth meal and the administration of apomorphine, which excites the vomiting center. The upper part of the stomach showed complete inhibition of its tone and appeared as a perfectly flaccid bag; the cardia relaxed. There then followed several deep peristaltic contractions which, commencing about the middle of the body of the organ, swept downwards toward the incisura angularis where they came to a standstill forming a sharp ring of constriction. From this point a weaker wave continued to the pylorus. Finally, a very deep, strong contraction at the incisura appeared to almost divide the stomach in two, the cardiac pouch and the cardia meanwhile remaining quite relaxed. A sharp contraction of the diaphragm and abdominal muscles then followed and ejected the gastric contents through the open cardia into the esophagus. The stomach played a more or less passive part in the process,⁴ its evacuation being effected by the strong compression to which it was subjected by the sharp descent of the diaphragm and the contraction of the abdominal muscles. Antiperistalsis was observed only once and then the wave did not proceed beyond the antrum. The deep contraction at the incisura offered an effectual barrier to the passage of stomach contents in a downward direction.

During the ejection of the vomitus the esophagus is relaxed throughout; the glottis is closed and the respirations are inhibited, the larynx and hyoid bone are drawn forward and are held rigidly in this position. The throat is thus enlarged to allow free exit for the stomach contents which are prevented from entering the naso-pharynx by the elevation of the soft palate.

Similar movements have been described in man. Definite antiperistaltic waves in the stomach are rarely seen, though violent churning movements may occur.⁵ According to Barclay, just

⁴ Magendie showed long ago that an active gastric element was not necessary for the vomiting act, since its essential features could be induced in animals after the stomach had been replaced by a pig's bladder.

⁵ In certain lower forms, however, e.g., the fish and the frog, which of course have no diaphragm, vomiting is carried out by the activity of the stomach alone, antiperistaltic waves carrying the food through the cardia. This more primitive type of vomiting, i.e.,

prior to the commencement of the vomiting movements, a sudden reduction of gastric tone occurs, the lower limit of the stomach dropping a couple of inches. This coincides with the sensation of nausea (p. 519) which ordinarily precedes vomiting. In certain types of vomiting, e.g., intestinal obstruction, or in persistent vomiting from other causes, antiperistalsis arises in the small intestine and sweeps material into the stomach or there may be a strong contraction of the duodenum which reverses the pressure gradient between the antrum and the duodenal bulb. Such movements of the duodenum occur some time prior to the actual vomiting or at the same time; it accounts for the fact that a short time after the stomach has been thoroughly washed out, bile-stained fluid or fecal material may be vomited. According to Alvarez, reverse peristalsis starting in the upper bowel is itself a potent cause of nausea and vomiting.

Relaxation of the cardia is an essential part of the vomiting act, for the stomach is subject to strong compression during coughing, defecation, etc., yet the gastric contents are not as a rule forced into the esophagus. The tone of the cardia is probably actually increased at these times. It has been mentioned that division of the vagi in animals causes the cardia to enter into a spastic state. Hatcher and Weiss found that if after such a procedure a vomiting reflex was initiated, mucus was expelled from the esophagus and the usual muscular movements were called into play, with the exception of relaxation of the cardia. That is, the animal retched but material was not expelled from the stomach. It is well known that with some persons vomiting is difficult while in others little distress is experienced. Differences in the degree of tone of the cardia are probably responsible for these individual peculiarities.

THE VOMITING CENTER

The vomiting center lies in the medulla in the neighborhood of the dorsal nucleus of the vagus nerve (p. 861). It is close to but distinct from the respiratory center. Vomiting is impossible after this area has been destroyed. The essential and accessory movements involve so

where reverse peristalsis and relaxation of the cardia are the prominent features, occurs normally in infants. The excess fluid of an oversized meal is regurgitated without the assistance, apparently, of the abdominal muscles or diaphragm; position and external pressure upon the abdomen following the meal sometimes, no doubt, also play a part.

many muscles that the center as in the case of the swallowing center probably serves the purpose of a receptive station for afferent impulses and a "control board" for various motor cranial nuclei. The *efferent* fibers are contained chiefly in the phrenics, the vagi and the sympathetics, but fibers are also conveyed by spinal nerves to the abdominal muscles and by cranial nerves to the muscles of the pharynx, palate, etc. The *afferent* impulses reach the center along a multitude of routes, the chief being the vagal and sympathetic fibers of the stomach and abdominal viscera.

THE INDUCTION OF VOMITING

The vomiting center may be excited (a) reflexly by impulses arising in the stomach, or some other part of the body, (b) by impulses received from cerebral centers, or (c) by chemical materials carried to it in the blood stream.

Vomiting of reflex and psychic origins

Mechanical and chemical irritants of various kinds act upon vagal or sympathetic afferent terminals in the gastric mucosa and initiate the vomiting reflex. Toxic materials taken in the food or formed during digestion may act in this way. Among the specific excitants of the vomiting act—*emetics*—are tartarate of antimony (tartar emetic), mustard, ipecac, mercuric chloride, copper and zinc sulphates, etc. Some of these have a selective action upon the terminations of one or other of the two groups of afferent autonomic fibers. For instance, tartar emetic, in the stomach, acts through the vagus but not through the sympathetic, since it fails to act after vagotomy, or after the vagal effect has been annulled by atropine. Mercuric chloride, on the other hand, acts more especially on the sympathetic mechanism since atropine does not prevent its emetic action, but ergotoxine which acts specifically by paralyzing sympathetic fibers, does. Mustard, salt and water, copper sulphate and zinc sulphate act upon both types of nerve.

Impulses arising from structures other than the stomach, particularly from other parts of the alimentary canal, are also powerful excitants of the vomiting center. It is well known that even mild mechanical stimulation of the pharynx or fauces is effective. Inflammation or mechanical disturbances in the intestine, e.g., appendicitis, obstruction, strangulation, etc., may induce violent emesis. Distension of the duodenum in a conscious animal induces vomiting movements.

Impulses arising in the kidney, bladder, uterus, gall-bladder, heart or any other viscus may induce vomiting quite independently of any condition within the stomach itself. Hatcher and Weiss have shown that several substances cause emesis through their action upon the heart, e.g., digitalis in large doses and pilocarpine. These drugs act apparently upon both vagal and sympathetic mechanisms. Tartar emetic also acts through the cardiac vagus as well as through the gastric nerves. These facts afford an explanation of the nausea and vomiting that occur in heart failure and in disease of the coronary vessels. Table 36 gives a summary of the afferent fibers involved in the vomiting reflex and the susceptibility of the two sets of fibers to the action of several drugs.

Severe pain, wherever located, strong emotion or impulses arising in the organs of special sense,

TABLE 36

DRUGS	AFFERENT AUTONOMIC FIBERS ACTED UPON	ORGANS CONTAINING SUSCEPTIBLE FIBERS
Mercuric chloride	Sympathetic and vagus	Stomach
Tartar emetic	Vagus	Stomach, duodenum and heart
Digitalis	Sympathetic and vagus	Heart
Pilocarpine	Sympathetic and vagus	Heart

e.g., those of smell, taste or sight, may cause vomiting. In the dog a *conditioned vomiting reflex* may be readily established by morphine injections (p. 908). Stimulation of the nerve terminals in the vertical semicircular canals (vestibular nerve) is considered the most potent factor in the causation of sea sickness, though impulses arising in the stomach itself or the retinae are contributory. In animals, the vomiting reflex is inhibited by certain other reflexes, e.g., the scratch and defecation reflexes. In man, the activity of the cerebral centers, e.g., sensations of disgust, anxiety, apprehension, worry, etc., enhance the tendency to sea-sickness, whereas interest or attention tend to prevent it. Benzadrine is among the best drugs in use for its prevention (see Albrecht).

"CENTRAL" VOMITING

Certain substances such as *apomorphine*, *emeline*, *picroltoxine*, when administered intravenously cause

vomiting through a specific action upon the center. These substances induce vomiting in animals when applied directly to the center. Typical vomiting efforts (retching) follow the injection of apomorphine after removal of the stomach and intestines. Emetics of this type are believed, however, to exert their effect by raising the excitability of the center rather than by direct stimulation of the nervous tissue. This is not merely an academic distinction but is of considerable interest from a practical point of view. Such an action is comparable to that in which strychnine acts upon the spinal centers. It implies that substances formed in the body in disease may raise the excitability of the vomiting center to a level where afferent impulses, ordinarily of sub-threshold value, may become effective for the initiation of the reflex.⁶ In other words, the so-called central type of vomiting is also essentially of reflex origin. General bodily conditions, e.g., mental stress, hysterical states or fatigue, may act similarly upon the excitability of the center. It is evident then that vomiting does not necessarily imply a primary disturbance of the gastrointestinal tract.

The persistent of pernicious *vomiting of pregnancy* is probably due to increased excitability of the center resulting from some metabolic disturbance. According to Harding the important factors in its production are carbohydrate starvation and dehydration with ketosis. Ordinary morning sickness is looked upon as a minor form of this condition, and differing from pernicious vomiting only in degree. As a result of the demands of the fetus, liver glycogen is low during pregnancy. After the fast of the night the reserves of carbohydrate are further reduced; a mild ketosis results which leads to nausea and vomiting. The distaste for food by hindering the replenishment of the carbohydrate stores aggravates the ketosis. Thus morning sickness merges insensibly into the pernicious type of vomiting. A neurotic element is also frequently a potent influence in the development and persistence of the condition. The obvious corrective measures are, high carbohydrate feeding, the free administration of fluids, injections of glucose if necessary, mild sedatives, rest and quiet.

Interference with the blood supply to the center, as by elevation of the intracranial pressure through tumor, etc., or by anemia or hemorrhage, may

⁶ It is of interest in this regard that substances formed in the body, e.g. adrenaline, choline, and histamine induce vomiting when applied directly to the center.

raise its excitability to the point where vomiting ensues. Vomiting associated with raised intracranial pressure occurs suddenly, is forceful and not preceded by nausea (projectile vomiting). Vomiting may be induced in animals by tying the carotid and vertebral arteries. The vomiting of mountain sickness is also a phenomenon associated with anoxemia (p. 360).

THE MOVEMENTS OF THE STOMACH IN HUNGER

The movements of the stomach during fasting have been studied by a number of observers, including Cannon and Washburn, and Carlson. The latter observer, in an exhaustive series of experiments has investigated the contractions and tonus changes of the empty stomach in various species of animals and in man. The movements were recorded by means of a thin rubber balloon introduced into the stomach and connected by tubing with a manometer containing water, chloroform or bromoform. A float placed upon the surface of the fluid carried a writing point by means of which the contractions were recorded upon a moving surface (fig. 206).

In man the movements of the empty stomach are of two types: (a) a *tonus rhythm* of the fundus and body and (b) the *hunger contractions* (fig. 207).

The tonus rhythm

The tone of the fundus and body of the stomach increases steadily as digestion progresses. When the stomach has been nearly emptied the tone is near its maximum, and shows rhythmical fluctuations. The tonus changes are never very marked features and require a rather delicate recording instrument to make them evident. They were not recorded in the earlier experiments of Cannon and Washburn. They have been observed directly by Carlson through a gastric fistula in man when the stomach was practically empty of food and contained no balloon or other foreign material. The rate of the tonus waves is slow, but very regular. They have a frequency of about 3 or less per minute.

The hunger contractions

These are powerful peristaltic waves which arise in the cardia and include the entire stomach. They commence about three hours after a meal, i.e., when the stomach is nearly empty, and are superimposed upon the tonus rhythm. The hunger contractions do not occur continuously,

FIG. .206 Diagram showing the method used to record the gastric hunger contractions. A, kymograph record of the increase and decrease of volume of the gastric balloon B; C, time records in minutes; D, record of the subjective experience of hunger pangs; E, record of the pneumograph placed about the waist. (From Cannon.)

FIG. 207. Upper, tracing of the tonus rhythm of the stomach (man) three hours after a meal. Lower, tracing from the stomach during the culmination of a period of vigorous gastric hunger contractions. (From Carlson)

but in series (hunger periods) separated by intervals in which the stomach, except for the tonus rhythm, is quiescent. The duration of each hunger period is usually from 30 to 45 minutes though it may continue for 1½ hours or be as short as 6 minutes.

The longer periods are found when the tonus of the fundus is high, the shorter ones are associated with a low tonus. The quiescent intervals last from $\frac{1}{2}$ to $2\frac{1}{2}$ hours. The duration of individual contractions is from 20 to 25 seconds, and their amplitude varies throughout the series. They are relatively feeble at the commencement, but become of maximal strength about the middle of the hunger period and die down again toward the end. Their frequency increases progressively throughout. At the beginning of the period they occur several minutes apart, but toward the end they succeed one another rapidly so that the intervening pauses are practically abolished and the muscle may pass into incomplete tetanus which usually lasts for from 2 to 5 minutes, but may be as long as 15 minutes. It occurs especially in young robust individuals, being unusual in older persons. Discomfort or actual pain (hunger pang) is associated with the contractions. In infants the tonus rhythm and the hunger contractions have been demon-

strated shortly after birth and before the stomach has been filled. When the contractions become well marked the infant wakes and cries.

During a fasting period in the human subject investigated by Carlson extending over a five-day period the hunger contractions showed no diminution. They, as well as the tonus rhythm, actually increased in amplitude, yet the hunger pangs and the general sensation of hunger became less after the third day. It is well known that the subjects of prolonged fasts experience little discomfort after the first few days and even the desire for food may pass.

The hunger contractions were found by Carlson to be inhibited by various means, e.g., smoking, compression of the abdomen, as by "tightening the belt," taking a quantity of water into the stomach, strenuous muscular exercise, and the application of cold to the surface of the body.

CHAPTER XLIV

MOVEMENTS OF THE ALIMENTARY CANAL (*Continued*); ABSORPTION FROM THE INTESTINES; THE FORMATION OF FECES; CONSTIPATION; INTESTINAL OBSTRUCTION

MOVEMENTS OF THE SMALL INTESTINE

Three types of muscular movements are usually described as occurring in the small intestine: (a) *peristalsis*, (b) *segmenting contractions*, and (c) *pendular movements*.

PERISTALSIS

This type of movement has already been mentioned as occurring in the esophagus and stomach. From a study of the peristaltic wave in the bowel Bayliss and Starling formulated the "*law of the intestine*," which states that a stimulus applied to a given point in the intestinal wall initiates a band of constriction on the proximal side and relaxation on the distal side of the stimulated point. The two phases, contraction and relaxation—excitation and inhibition—were described as traveling down the bowel at the same rate, constituting a wave which swept the intestinal contents before it. It is questionable, however, whether relaxation of the bowel on the distal side of the stimulated point actually occurs. Henderson was unable to demonstrate it in the intestine of either the guinea-pig or rabbit, a simple constricting ring being the only movement observed. The natural stimulus to peristalsis and other types of intestinal movement is the distension of the intestinal wall caused by the food mass within its lumen. Quigley and associates have shown that a bolus is propelled along the bowel in a spiral fashion. They inserted a bolus of cotton to which two long threads of different colors were attached and found that the rotation occurred in an anti-clockwise direction. The length of bowel traversed in making a full rotation (360°) was from 23 to 35 cm. The bolus was propelled along the intestine (ileum) at an average rate of 9 cm. in 8 or 9 minutes.

It has been mentioned that waves may be seen passing in an oral direction (antiperistalsis) in the duodenum (p. 490). For a variable distance above the ileocolic valve antiperistalsis also occurs, and appears to serve as a check to the too rapid passage of ileal contents into the cecum. With these exceptions, peristalsis normally travels only in an aboral direction. That the small intestine

for the most part is incapable of transmitting peristaltic waves in the opposite direction was demonstrated by Mall. He resected a segment of the small bowel and then restored the continuity of the tube by suturing the resected portion in the reverse position. Peristaltic waves travelled from below upwards in the reversed loop, and obstruction occurred due to the accumulation of food at the upper suture line. Cannon in a similar experiment also observed that the reversed loop offered a barrier to the passage of the food. He saw, in addition, the food carried toward the pylorus in the normal segment of intestine above the loop. This latter observation is in accord with the belief that reversed peristalsis occurs in pathological conditions, e.g., intestinal obstruction, and is responsible for the passage of fecal material into the stomach. It should be mentioned, however, that if the reversed loop be quite short peristaltic waves arising in the normal bowel above may simply push material through it as though it were an inert tube. Also it has been reported that if the animal survives the operation for a sufficient length of time (several weeks), the reversed segment may adapt itself to the altered conditions and move the food downward by true peristalsis (i.e., antiperistalsis in so far as the inherent ability of the bowel is concerned).

In animals examined by means of X-rays, peristalsis is not as a rule of frequent occurrence and when waves do appear they follow, not in a regular series, but at odd intervals. The peristaltic movements are of two types. *First*, a slow, gentle wave which moves sluggishly along the bowel at a rate of from 1 to 2 cm. or less per minute, may be seen from time to time. This transfers food masses, which have already been subjected to the more active segmenting movements, for short stretches along the intestine. *Secondly*, a swiftly moving peristaltic wave appears from time to time and coursing down the bowel for longer or shorter distances, sweeps all before it and then dies out. The food is left for a later wave to carry it further; the food is thus conveyed along the bowel in relays. This type of movement is spoken of as the "*peristaltic rush*." Its speed

may be anywhere from 2 to 25 cm. per second, the farther it goes the greater speed it attains; the average rate is about 10 cm. per second. The length of bowel traversed by any wave varies in accordance with the general state of activity of the bowel at the time and with the strength of the stimulus. After a strong cathartic, or as the result of some intense stimulation of the gastrointestinal tract as by an irritant poison, for example, the wave may sweep with great rapidity from pylorus to anus, completing the entire journey in a minute or less.

Experiments made upon animals show that a rush may be initiated by conditions within the stomach or even by an act of swallowing, and one of the most effective means of producing such a movement in the intestine is to have the animal drink. In some instances the rush is evidently started by the passage of material through the pylorus into the duodenum, but in many others, though a peristaltic wave appears in the stomach this does not reach the pylorus before a rush commences in the duodenum. This fact, and the observation that a swallowing act alone will start a rush indicates that in many instances the mechanism is essentially reflex in nature. A peristaltic rush in the small intestine is frequently followed by a similar though independent movement (mass peristalsis) in the colon (p. 499).

In the human duodenum, following a barium meal, peristalsis is not a prominent feature. Yet the duodenal contents are, nevertheless, being constantly moved onwards. Barclay suggests that this is due to contraction of the muscularis mucosae, the mucous membrane being raised into transverse fold which ripple along the lumen of the bowel.

THE SEGMENTING MOVEMENTS

When the abdomen of an animal is opened and the coils of intestine floated upon a warm saline bath in order to obviate the effects of cooling and drying, rhythmical contractions of the bowel wall may be seen. The movements consist of simple constrictions of the tube, resulting from sharp contractions of the circular coat of the bowel. The annular constrictions do not progress along the bowel, and cause little or no translation of the food.

According to Cannon the segmenting movements in an animal given an opaque meal and examined radioscopically appear in groups of simultaneous constrictions spaced regularly along the bowel.

The groups succeed one another rhythmically at the rate of from 20 to 30 per minute. They divide the intestinal contents into numerous small sections which are redivided by the next group which follows. The halves of adjacent segments so divided flow together to form fresh masses which are in turn bisected and reformed by the fusion of the divided parts. This process is repeated over and over again and the rhythmical kneading of the food results in a thorough mixture of its constituents with the digestive juices. It also encourages the absorption processes by continually brining the chyme into contact with fresh mucous surfaces; and by the massaging effect of the movements upon the bowel wall, the flow of lymph and blood through the lacteals and capillaries is hastened. The segmenting movements have been observed by Hertz and others in the human intestine by radioscopy but their rhythm was slower—about 8 per minute.

PENDULAR MOVEMENTS

These like the segmenting movements are simple annular constrictions. They travel up and down short lengths of the bowel in a to and fro fashion at a rate of about 5 cm. per second. They have the effect of carrying the chyme alternately from one to the other end of a loop of bowel. Their frequency is from 20 per minute in the duodenum to about 10 per minute in the lower ileum. The pendular movements are not always well marked. They are best seen in the rabbit, though they occur also in other animals and sometimes in man. At times they are very active and appear to throw the food material rapidly and with considerable force from end to end of a small section of the bowel. They constitute another factor contributing to the thorough mixing of the food; they have no direct effect upon the movement of food through the digestive tube, but exert a purely local churning or "shaker-like" action.

MOVEMENTS OF THE INTESTINAL VILLI

If the intestinal mucosa of a living animal be exposed and examined under the low power of the microscope the villi can be seen to be in constant motion—swaying from side to side, shortening and elongating alternately, or lashing to and fro, either singly or in groups. The movements are due apparently to rhythmical contractions of smooth muscle fibers situated within the villi. By constantly stirring the fluids which bathe the surfaces of the villi, these movements undoubtedly

aid the digestive and absorptive processes (see also pp 453 and 504).

THE METABOLIC GRADIENT THEORY OF ALVAREZ

Alvarez believes that the fundamental factor determining the polarity of intestinal peristalsis is the gradual diminution in the metabolic activity of the intestinal muscle that occurs from the duodenum downwards. A parallelism was found between the magnitude of the energy exchanges of the bowel at different levels and its muscular activity. Rhythmicity, irritability and force of contraction and tone are graded from above downwards, being high in the duodenum and low in the ileum. The length of the latent period of the muscle also shows an increase as the intestinal tract is descended. The carbon dioxide production and oxygen consumption exhibited a corresponding decrease from the duodenum to the lower reaches of the intestine. The frequency of the rhythmical segmenting contractions (p. 497) is 17 per minute in the duodenum but only 10 in the lower ileum. Warming a strip of ileum raises its metabolism; its rate of beat is increased to equal that of the duodenum while the latent period is shortened. The decline in the metabolic rate from duodenum to ileum is spoken of by Alvarez as the *metabolic gradient*; to it are ascribed the progressive diminution of the other physiological activities of the muscle. Upon the difference between the intensities of the latter at any two levels of the digestive tube, the direction and swiftness of the peristaltic wave are supposed to depend. Alvarez suggests in illustration of his conception, water flowing between two regions of unequal pressures. When the gradient has the normal slope, peristalsis is active and downward in direction. An inflammatory or irritative lesion, however, according to this observer, may raise the metabolic rate at a certain point so that it approaches, equals, or rises above that at a point nearer the pylorus. In such a circumstance the gradient would become reduced, annulled or even reversed. Sluggish peristalsis, stasis or antiperistalsis, respectively would result. Reversal of the gradient and the production of antiperistalsis as the result of mechanical blockage of the lumen, or injury and inflammation of a region of the bowel are advanced to explain the passage of fecal material into the stomach in intestinal obstruction and paralytic ileus.

The theory is interesting and suggestive. It accords with many experimental and clinical observations, but cannot be said to have been established.

THE ILEO-COLIC VALVE (VALVULA COLI)

This structure when competent permits the passage of the contents of the small intestine at intervals into the cecum, but hinders the return of the material into the ileum. Its ability to do this depends, according to one view, not upon any mechanical valve-like device, but upon the con-

traction of the circular fibers of the gut which are thickened in this region to form a sphincter guard for the ileo-cecal orifice. Most observers agree, however, that the competency of the ileo-colic valve is actually due to a valve-like construction. The ileum enters the cecum obliquely and in doing so invaginates the cecal wall; this alone would tend toward a valve-like action. The valve proper is formed as follows. As the lower end of the ileum enters the cecum, the invaginated portion of the cecal wall forms two transverse folds or lips, one above the other below the ileo colic orifice. The lips fuse laterally to produce a fold on either side of the orifice (*the frenula coli*) which are continued around the interior of the

FIG. 208. X-ray photograph of normal large bowel completely filled. (After Barclay.)

cecum. As the cecum distends the frenula are stretched and pulling upon the lips from either side draw them firmly together. Thus the valve can withstand a high pressure in the cecum but yields to a low pressure from above. Material introduced by enema may in some instances pass through the sphincter into the ileum. Such incompetence may permit the enema fluid to reach the duodenum. The ileo-colic opening has been observed in man through a cecal fistula. It appears as an oval or round opening from 2 to 3 cm. in diameter situated in the center of a small papilla. When contracted the sphincter was found to offer considerable resistance to the passage of the finger. While digestion was in progress the papilla was observed to flush, its color altering from a pale pink to a vivid red. The sphincter opened rhyth-

mically at frequent intervals and allowed a jet of fluid to escape into the cecum. Emotional excitement or the swallowing of food increased the frequency of the ejections. During fasting nothing passed through for long periods, but in from $\frac{1}{2}$ to 4 minutes after food was taken into the mouth, fluid appeared in gushes of about 15 cc. every half minute or so.

The functions of the sphincter appear to be (a) to prevent the contents of the ileum from passing into the cecum before the digestive processes are complete (see also antiperistalsis in ileum, p. 496), and, (b) to act as a barrier which prevents the bacteria-laden contents of the large bowel from contaminating the small intestine.

THE MOVEMENTS OF THE LARGE INTESTINE

The contents of the ileum after passing through the ileo-colic orifice collect in the blind end of the cecum. In the human cecum little or no movement can be seen, as a rule, yet the material passes slowly into the ascending colon. This is due in part to filling of the cecum and passive overflowing but in many instances the material appears in the ascending colon *before* the former becomes filled. The forces bringing this about are not known. Todd describes slow changes in the shape of the cecum but thinks such a movement inadequate for the propulsion of its contents. Barclay remarks upon the absence of activity in man which, as he expresses it, presents a picture of "still life." In animals constricting rings may be seen passing over the cecum driving material against its blind end. These have the effect of churning the contents. Such antiperistalsis though not seen normally in the human cecum may, according to Todd, appear when the colon beyond is in a spastic state.

The rest of the human large intestine as revealed by radioscopy is usually free from antiperistaltic, segmenting or pendular movements; and peristalsis is absent or ill-defined. Some hours after a meal the shadow cast by the ascending, transverse and descending colons has usually a segmented appearance—a number of short sections strung together (fig. 208). This appearance is caused by the haustra or sacculations in the bowel wall. Todd describes slow weak peristaltic movements and alternate shortenings and elongations—concertina-like action—in the transverse colon.

MASS PERISTALSIS

This is a movement first described by Holtz-knecht which occurs from time to time in the

colon and sweeps the contents *en masse* for considerable distances along the bowel. The movement is analogous to the peristaltic rush already described as occurring in the small intestine. The mass movement in the colon of which the subject is quite unaware occurs only at long intervals, probably not oftener than two or three times in twenty-four hours. It is frequently preceded by the corresponding movement in the small intestine. It may occur almost immediately after the entrance of food into the stomach—*gastro-colic reflex*. The desire to stool so commonly experienced after breakfast is the result of this reflex; fecal material is forced into the rectum and the defecation reflex initiated (p. 503). Mass peristalsis in the colon may also be induced by purely psychic influences—the taste, smell or thought of food or some disturbing emotion. Alvarez cites an instance of a subject with an incompetent anal sphincter in whom a bowel movement could be precipitated by the mention of savory food.

The movement usually starts in the region of the hepatic flexure. The haustral markings suddenly disappear, the bowel appearing radiologically as a solid unsegmented column. A strong and rapid peristaltic wave then travels over the transverse and descending colons carrying all before it. The haustral markings then reappear (fig. 209). The contents of the more proximal portion of the colon are thus transferred to the pelvic colon which becomes filled from below upwards. The pelvic colon serves as a storehouse for the feces; it is evacuated through the rectum and anal canal by the act of defecation. The descending colon is usually empty except during the time that the feces are being transferred by a mass movement. Feces after they have filled the pelvic colon may, however, extend upward into the descending colon, and may even reach the splenic flexure. Except preceding and during the act of defecation the rectum also is normally empty.

DEFECATION

The act is brought about by the passage of fecal material past the resistance of the pelvi-rectal junction. According to some observers a definite thickening of the circular fibers of the colon (pelvi-rectal sphincter) exists in this situation. The entrance of the feces into the rectum may result from a mass movement already described or simply from overloading of the pelvic colon and the gradual pushing of its contents downward. The fecal masses fill and distend the rectum, and,

when the intra-rectal pressure reaches to between 40 and 50 mm. Hg, the defecation reflex occurs. The reflex consists of a strong peristaltic contraction of the colon, accompanied by shortening of its longitudinal fibers which are disposed in three bands—*taeniae coli*—on its anterior, inner and posterior aspects. The tenia obtain fixed points for their contraction indirectly from the coccyx, through the recto-coccygeus muscles. The latter arise from the coccygeal vertebrae and blend at the lower part of the rectum with the longitudinal fibers of bowel which in this situation have become

FIG. 209. Holzknicht's diagrams of the happenings during a mass movement of the large intestine. 1, distribution of the food before any change was noted; 2, the haustral segmentation in the transverse colon has disappeared; 3, the whole colon beyond the hepatic flexure passes on suddenly; 4, it is again a picture of "still life" a few seconds later and the haustral segmentation has returned. (After Barclay.)

spread out to form a continuous sheathing for the rectum and anal canal. The contraction of the longitudinal fibers and consequent shortening of the bowel combined with the simultaneous downward progress of the peristaltic wave, and a coördinate relaxation of the anal sphincters, effects the evacuation of the feces. Hurst made observations upon human subjects by means of the X-rays and found that the evacuation of the colon extended as far or even beyond the splenic flexure. The movements of the bowel wall itself are accompanied and assisted by the contraction of voluntary muscles. The diaphragm

descends to its extreme inspiratory position and is held there, the glottis being kept closed during the straining efforts which follow. The abdominal muscles contract powerfully and the intra-abdominal pressure rises. The descent of the diaphragm, as Hurst has shown, causes marked depression of the ascending and transverse colons and of the splenic flexure. The compression of the ascending colon against the nearly stationary cecum forces the former into an almost globular form. The pressure in the rectum, which in an individual in the erect posture amounts at ordinary times to about 20 mm. of mercury, rises to from 100 to 200 mm. during the straining efforts. The pelvic floor is supported against the elevated intra-abdominal pressure by the contractions of the levatores ani, the transverse perinaei and coccygeus muscles. The levatores ani, which pass from the origins downwards on either side of the rectum and anal canal have some of their fibers inserted into the walls of these portions of the bowel and into the fibrous tissue in the neighborhood. By their contraction the anus is drawn upwards over the fecal mass. They also prevent prolapse of the rectum and anal canal, and by constricting the walls of the latter, at the termination of the act effect the expulsion of any material still remaining. The levatores ani serve also to reinforce the sphincters against the action of strong peristaltic waves and so enable the individual, when necessary, voluntarily to resist the evacuating reflex (see also p. 503)

The rate of progress of a barium meal through the human intestinal tract

The time required for the first part of a barium meal (semi-fluid) to pass from the stomach to the pelvic colon varies in different individuals. The usual time is from 12 to 14 hours. The material commences to leave the stomach almost immediately after it has been swallowed; it moves steadily and at a fairly rapid rate through the duodenum and very rapidly through the jejunum. Its progress through the ileum becomes progressively slower as the ileocecal opening is approached and in the lower part of the ileum the material tends to accumulate before it is passed into the cecum. It commences to enter the latter in about 2½ hours on the average. In 4 hours or so the material arrives at the hepatic flexure, and in about 6 hours at the splenic flexure.

Evacuation occurs at variable times after the material has commenced to collect in the pelvic colon but occurs usually in from 16 to 24 hours after the meal has entered the stomach. The first parts of the meal appear in the stools about 24 hours after the food has

entered the stomach and the last tracers in from 36 to 48 hours.

Many factors influence the rate of progress of food along the intestine—(a) The chemical and physical characters of the food. (b) Individual variations in the activity of the intestinal musculature, or in the absorptive function of the colon, and consequently, in the consistency of its contents. (c) The state of fullness of the alimentary tract. After a fast or after the bowels have been cleared by a cathartic the intestinal contents move more rapidly but the time elapsing before it is evacuated may appear to be longer than usual, since the pelvic colon takes time to refill. (d) Muscular exercise increases the rate of movement. (e) Emotional states also tend to increase intestinal activity.

THE ACTIONS OF CERTAIN SUBSTANCES UPON INTESTINAL MOTILITY. Fats, through the production of glycerine and soaps, stimulate the movements of the small bowel; sugars are also excitatory. Acetylcholine and pilocarpine or eserine, given intravenously, are powerfully stimulant. Pituitrin is also excitatory whereas adrenaline is inhibitory.

Atropine reduces the tone of the musculature of the small and large bowel and relieves intestinal spasm. The phasic contractions of the small bowel are also usually decreased in amplitude but sometimes appear to be increased, in any event the propulsive force of the contractions are diminished, so that the progress of material along the intestinal lumen is slowed. The movements of the large bowel, especially of the distal colon, are depressed. Morphine increases intestinal tone; the rhythmical movements (segmenting and pendular) are increased in frequency, but reduced in amplitude. The propulsive movements are profoundly depressed or abolished; constipation results.

THE NEURO-MUSCULAR MECHANISMS GOVERNING THE MOVEMENTS OF THE INTESTINAL TRACT

INNERVATION OF THE SMALL INTESTINE

The wall of the small bowel is composed of an outer longitudinal and an inner circular coat. The latter is considerably thicker than the former. According to Carey both coats are arranged in a spiral fashion. Between the two muscular sheets the *myenteric plexus* (Auerbach's) is situated. The *plexus of Meissner* lies in the submucosa. These two plexuses are connected with one another by nerve filaments which pass between the circular muscular fibers. Auerbach's plexus contains numerous ganglion cells; which are scarce in Meissner's plexus.

The rhythmical contractions—*segmenting* and *pendular*—are myogenic, that is, they are dependent solely upon the rhythmical property of the intestinal muscle itself. They are not abol-

ished by such nerve poisons as cocaine and nicotine. A segment of excised intestine beats rhythmically when immersed in a 1 to 4000 cocaine solution. Furthermore, the contractions of the circular coat of the bowel have been shown by Gunn and Underhill and by Alvarez and Mahoney to continue after it has been stripped from the longitudinal layer, and from the submucosa as well; all ganglion cells are in this way removed. (See also Gasser, and Thomas and Kuntz.)

FIG. 210. Upper, shows the inhibitory effect of splanchnic stimulation upon the movements of the small intestine; the heavy white line indicates the time during which the stimulus was applied (after Starling). Lower, shows effect upon intestinal motility of stimulating vagus nerves. (After Thomas and Kuntz.)

The peristaltic contractions, on the contrary, are dependent upon the intrinsic nerve plexuses. But though carried out through local reflexes in the bowel wall (myenteric reflexes of Cannon) they are readily influenced through the extrinsic nerves—the *vagus* and *sympathetic*. It was shown by Bayliss and Starling that section of both these sets of nerves does not abolish the peristaltic movements, whereas the application of cocaine to the bowel wall does. The *vagus*, whose terminals connect with ganglion cells in Auerbach's plexus, augments the movements. The *sympathetic* is inhibitory (fig. 210). The sympathetic fibers pass mainly in the lesser splanchnic nerve

to the lower part of the celiac ganglion and to the superior mesenteric ganglion (fig. 205); from these ganglia the impulses are relayed to the bowel. The postganglionic fibers pass without interruption through the plexuses of the bowel wall to end in direct relation with the muscle cells. The extrinsic nerves also influence the tone of the intestine, the vagus increasing, the sympathetic diminishing this property. The sympathetic exerts a continuous inhibitory action upon the bowel movements which are therefore augmented after section of the sympathetic fibers. It has also been shown by Campbell and Markowitz that spinal anesthesia which temporarily paralyzes the thoraco-lumbar outflow removes the reflex inhibition of the intestine induced in dogs by peritoneal irritation (intraperitoneal injection of tincture of iodine). The vagus on the other hand does not appear to exert any continuous augmentor effect upon intestinal motility, for section of these nerves does not affect the movements.

INNERVATION OF THE COLON

In the cecum and the rest of the colon the fibers of the outer muscular coat are gathered into three longitudinal bands—the *taeniae coli*—which, being shorter than the underlying layer, draw the bowel into the tucks and pockets known as haustra. The circular coat is thickened between the latter. The intrinsic nerves (plexuses) of the colon have a distribution similar to that of the small intestine.

The extrinsic nerves

For a variable distance from its commencement the large intestine is supplied with motor fibers through the vagus. The vagal innervation terminates usually within the first half or third of the transverse colon. The rest of the colon, including the rectum, receives its motor innervation through the pelvic nerves (*nervi erigentes*, p. 942) from the 2nd, 3rd and 4th sacral segments. The pelvic nerves are cholinergic.

Inhibitory fibers to the entire colon are derived from the *sympathetic*. They arise from the lumbar segments of the cord and reach the proximal part of the colon (cecum, ascending and transverse colons) through the inferior mesenteric plexus (p. 940). The fibers to the distal colon (descending, iliac and pelvic colons and rectum) arise from the 2nd and 3rd lumbar segments. They pass via the lumbar splanchnics to the inferior mesenteric ganglion and thence to the bowel by (a) a number of short strands called

the *lumbar-colonic nerves* (also known as *inferior mesenteric nerves*) and (b) the *hypogastric (presacral) nerve*. The lumbar-colonic nerves are the axons of cells situated in the inferior mesenteric ganglion.¹ The fibers entering into the formation of the hypogastric nerve pass for the most part without interruption through the lumbar ganglion. Their cell stations are situated in the hypogastric ganglion. The postganglionic fibers pass through the pelvic plexus to the bowel (fig. 205, 211). The hypogastric nerves, and probably the lumbar colonic nerves as well, are adrenergic.

FIG. 211. Diagram of the innervation of the distal colon.

Stimulation of the lumbar-colonic nerves causes relaxation of the distal colon. Learmonth and Markowitz showed that these nerves exert a constant inhibitory action since increased color activity follows their section. Garrey found that though in the decerebrate cat the distal colon is inactive when its sympathetic supply is intact, division of the lumbar-colonic nerves causes rhythmic activity and a marked increase in tone. The hypogastric nerve appears to exert a minor inhibitory influence upon the colon since its division causes only a slight increase in the activity of the bowel. Paralyzing the lumbar outflow with a spinal anesthetic has an effect similar to that

¹ According to Learmonth there can rarely be found in man, a definite structure to which this name can be applied.

nerve section.² The inhibitory impulses of the colon arise apparently within the lumbar cord, for if this region has been isolated previously from higher centers by spinal transection the full augmentor effect upon the colon of sectioning the colonic nerves is obtained.

Section of the *pelvic nerves* (sympathetic innervation intact) relaxes the wall of the distal colon and the animal subsequently experiences difficulty in emptying the bowel. The effect of section of the pelvic nerves upon the tone of the colon is particularly well shown if the bowel has been previously in a hypertonic state as a result of division of the sympathetic supply. Section of the cord above the sacral segments also causes relaxation which indicates that the constant augmentor effect is due to impulses arising in higher centers. A subsidiary augmentor center apparently exists, however, in the sacral cord, for cutting the pelvic nerves some time after spinal transection causes colonic relaxation. That is, the sacral segments acquired control during the time which had elapsed after their isolation from higher centers.

INNERVATION OF THE SPHINCTERS

The sphincters of the bowel—ileo-colic, and the internal and external anal sphincters—exemplify the principal of reciprocal innervation, or what Meltzer termed when speaking of muscular tubes, "contrary innervation." For instance, the motor nerve to the *ileo-colic* sphincter is the same as that which causes inhibition of the bowel wall, namely, the sympathetic. Stimulation of this nerve will in consequence produce a dual effect, contraction of the sphincter and inhibition of the wall of the ileum. In this way the passage of fluid into the cecum is restrained. Logically we should expect the vagus to have an inhibitory effect upon the ileo-colic sphincter, but this action has never been demonstrated, and so far as is known the vagus is without any effect upon the sphincter.

The *internal anal sphincter* is also innervated in a fashion contrary to that of the rest of the large bowel. The pelvic is the inhibitory nerve, while the sympathetic is motor. The sympathetic fibers are conveyed via the lumbar-colonic and hypogastric nerves. Stimulation of parasympathetic fibers will therefore induce evacuation of the bowel by excitation of the bowel wall and relaxation of the sphincter. Stimulation of the

sympathetics on the other hand inhibit intestinal activity and increase the tone of the sphincter; the act of defecation will be restrained. The *external anal sphincter* is composed of striated muscle; it is kept tonically contracted and is under voluntary control. It is said not to atrophy when its nerve supply (derived through the 4th sacral nerve and the perineal branch of the pudendal nerve) is cut, but to recover its tone to a large extent after the operation. Its contraction, with that of the levator ani and other perineal muscles, is an important factor in opposing defecation. Afferent impulses arising in these muscles during their contraction are said to reflexly inhibit the bowel movements.

THE INNERVATION OF THE MOVEMENT OF DEFECATION

The defecation reflex is governed by a medullary center and a subsidiary center in the cord. The existence of the latter is evident in nervous diseases associated with complete functional or anatomical division of the cord above the lumbosacral region, when evacuation is effected automatically and in an almost normal manner. Also in animals after complete transection of the cord, though there is loss of control over the bowel movements and incontinence of feces for a time, the spinal center subsequently assumes control and automatically evacuates the bowel at regular intervals.

The *spinal center* is situated in the second, third and fourth sacral segments, but the destruction of this region in animals is not necessarily followed by complete and permanent fecal incontinence, for the rectum like the bladder (p. 415) is capable of controlling evacuation through its intrinsic nervous mechanisms. Also in involvement of the sacral segments of cord in man there sometimes may be almost perfect automatic control of the rectum and anal sphincter.

The *medullary center* is situated in the floor of the fourth ventricle not far from the vomiting and respiratory centers; Hatcher has shown that a stimulus to defecation will inhibit vomiting and certain emetic drugs (picrotoxin) applied to the vomiting center cause defecation. Hatcher and Weiss found areas in the medulla which controlled the tone of the sphincters. The well known fact that stimulation of the anal sphincter by forcible dilatation is an effective means of stimulating respiration, suggests a close relationship between the respiratory and defecation centers.

² It is likely that the center for the sacral outflow is also paralyzed by the anesthetic but that the bowel movements are then controlled by the intrinsic plexuses.

The reflex as mentioned on page 499 is initiated under normal circumstances by the passage of feces into the rectum. The latter, however, soon adjusts its capacity to the bulk of the feces (postural tone) the pressure stimulus being then abolished. The rectum may therefore become unresponsive³ if defecation is voluntarily prevented. The afferent fibers conveying impulses from the rectum travel mainly if not entirely with the efferents of the pelvic nerve and enter the cord by the posterior roots of the sacral nerves. Afferent fibers supplying the anal canal probably travel in the pudendal nerves. Division of the main afferent paths abolishes the defecation reflex since no impulses can reach the center. There is retention of feces for a time, but as mentioned above the local nervous mechanisms of the bowel wall later assume control.

THE REACTION OF THE INTESTINAL CONTENTS

The reaction of the contents of the duodenum vary considerably in accordance with the acidity of the chyme entering from the stomach and with the volume of the alkaline fluids—especially of the pancreatic juice. The proportion of acid and alkaline fluids varies in turn with the stage of digestion and the type of food, meat tending to increase the acidity of the chyme. In the dog the pH of the duodenal contents may be anywhere from 4.6 to 7.6; the usual value is about 6.⁴ In the human subject, the type of food and differences in the secretory activity of the gastric glands cause considerable individual variations in the reaction of the duodenal contents; in subjects of subacidity or hyperacidity (p. 442), for example, the reaction tends to be more alkaline or more acid, respectively. Samples of human duodenal contents, obtained by duodenal tube, show in most cases a pH between 5 and 6, average about 5.5. In subjects of duodenal ulcer, the pH of the contents of the duodenal bulb during fasting is about 4. Determinations upon healthy animals (rats and dogs) indicate that the contents of the entire small intestine below the duodenum are almost always definitely acid in reaction. From observations made upon patients with intestinal fistulae, this is most probably true also of the human intestine. The acidity of the small intestine (except in its upper part) is due to organic acids resulting from the action of fermentative types of bacteria (p. 510). In rats there

occurs a progressive rise in pH from the upper to the lower levels of the small intestine. The average pH of the contents of the former is around 6 and of the latter about 6.8. The pH falls slightly in the cecum but rises again in the colon. The feces have a faintly acid, neutral or a faintly alkaline reaction (6.9 to 7.2). In rachitic animals the pH of the intestinal tract and the feces is higher than that of normals. The administration of cod-liver oil or exposure to sunshine restores the reaction to the normal level. (Zucker and Matner)

ABSORPTION FROM THE GASTRO-INTESTINAL TRACT

Alcohol is absorbed from the stomach, but water, glucose and other materials in only negligible amounts pass through the gastric mucosa. The absorption of food materials is practically confined to the small intestine. Absorption from the colon is restricted mainly to water and inorganic salts. Glucose solution (10 per cent) introduced by enema may be absorbed in considerable amounts but the absorption of proteins and fats is for practical purposes (rectal feeding) unimportant. The absorption of the different food materials from the small intestine is considered in the respective sections dealing with the metabolism.

The villi are the absorbing units of the small intestine. Each of these minute finger-like processes is covered by a layer of columnar epithelium, and contains a capillary loop and lymph vessel (lacteal), a small amount of connective tissue and strands of smooth muscle. There are some 5,000,000 villi in the human intestine which provide a total absorbing surface of some 10 square meters (fig. 196, p. 453). Amino-acids and glucose are absorbed into the capillaries; about 60 per cent of the digested fat can be recovered from the thoracic duct; the remainder is absorbed apparently into the portal blood.

Attempts have been made to explain intestinal absorption by known physico-chemical laws. The factors of a physico-chemical nature whereby absorption might conceivably be brought about are: (a) Differences in concentrations and therefore of the diffusion pressures between crystalloids in the blood and in the intestinal lumen. (b) The hydrostatic pressure within the intestine created by the intestinal movements, which would tend to drive water and dissolved substances across the epithelial boundary. Hamburger found that absorption varied directly with the intraluminal intestinal pressure, and Wells has shown that the absorption of water from isotonic sodium chloride

³ This was well shown in the human subject by Hurst. When the rectum was inflated the call to defecate became urgent, but the intrarectal pressure fell again within half a minute or so, as a result of the adaptation of the rectal walls to the distending force, and the sensation passed off. Rapid re-inflation caused the sensation to return and then pass away again as the pressure fell.

⁴ It will be noted that this is not the optimum pH for the action of the pancreatic enzymes.

ride solutions ceased when the intra-intestinal pressure was reduced to from 8 to 26 cm. below that of the atmosphere, but that the absorption rate increased in proportion to the increase in intra-intestinal pressure above this level. (c) The osmotic pressure of the plasma proteins in excess of the hydrostatic pressure of the capillary blood pressure was suggested by Starling as an important factor in attracting water and crystalloids into the blood stream. It has been estimated that the colloid osmotic pressure is some two or three times greater than the blood pressure in the capillaries of the villus. (d) Hober suggests that electrical forces in the nature of cataphoresis (the transfer of a solute across a membrane from anode to cathode) play an important rôle.

Though some or all of the factors enumerated above probably play a part in the absorption process, there are several observations which cannot be explained upon a purely physico-chemical basis, some specific "vital" activity must be attributed to the epithelial cells of the villi. For example, materials such as glucose and sodium chloride are absorbed from hypotonic solutions (i.e., solutions containing the material in lower concentration than it exists in the plasma). Also, as shown by Cori, the absorption of glucose from the intestine may continue at a practically constant rate for hours though its concentration diminishes progressively; on the other hand, the absorption of a material, such as glucose, can not be increased by simply reducing its concentration in the plasma. Such facts cannot be explained by the laws of diffusion. Moreover, Hewitt has shown that when glucose, galactose and fructose in equivalent concentrations are placed in an intestinal loop the relative absorption rates are glucose > galactose > fructose. After destruction of the epithelial lining all three sugars are absorbed at the same rate. Macleod and associates found that glucose was absorbed more rapidly from a surviving intestinal segment than the foreign sugars xylose, mannose and arabinose. This preferential absorption of glucose disappeared when the temperature of the segment was lowered to 0°C. The sugars then passed through the intestinal wall in accordance with their diffusion rates through a dead membrane—xylose with the smaller molecule diffusing more rapidly than glucose.

That the epithelial covering of the villus is not merely a passive membrane, but performs a specific function which entails the expenditure of energy, is also indicated by the experiment of Bro-

die, Cullis and Halliburton. They observed an increase of over 150 per cent in blood flow, oxygen consumption and carbon dioxide production during the absorption of salt solutions of different concentrations. They concluded that a specific function of the epithelial lining, rather than contractions of the wall of the intestine was responsible for the increased metabolism. In the more recent experiments of Van Liere and his colleagues, it was found that oxygen lack does not impair the absorption of all substances alike. Anoxic anoxia to a degree compatible with life does not reduce the absorption of glucose and actually increases the absorption of glycine. Nor is the absorption of sodium sulphate reduced by anoxia. A phosphorylation process rather than an oxidative one is probably concerned in the absorption of glucose, which would account for its being unaffected by anoxia. Anoxic anoxia definitely depresses the absorption of sodium chloride, but anoxia produced by hemorrhage actually increases absorption of isotonic salt solution.

Any consideration of intestinal absorption recalls the process of selective reabsorption by the cells of the renal tubules and suggests that similar factors are concerned. That the cells of the intestinal mucosa perform chemical work, as in the absorption of fat (p. 599) is accepted. Reabsorption of water and dissolved substances from the glomerular filtrate is, one might say, a process of reverse secretion—from tubular lumen to blood. The laws of diffusion are just as inadequate to account for the absorption from the intestinal lumen as they are to explain the reabsorption process in the kidney.

THE FORMATION OF FECES

The contents of the ileum have an almost liquid consistency. The quantity of fluid material passing through the ileo-colic valve in 24 hours is in the neighborhood of 400 grams. The feces evacuated during an equivalent length of time is about 150 grams. The fluid is absorbed mainly by the cecum and ascending colon, but also in smaller amounts during the progress of the feces along the transverse and descending colons and during their stay in the pelvic colon. The feces are neutral, slightly acid or slightly alkaline in reaction (p. 504).

The feces are composed of food residues, bacteria, material secreted through the wall of the intestine and in the bile, leucocytes and desquamated epithelial cells. Food residues constitute a much smaller proportion of the bulk of the feces than

is usually realized. The fat, protein and carbohydrate of the diet is practically all absorbed and if the food be free from indigestible material, especially cellulose, the feces are composed almost entirely of bacteria, secretions, etc. During starvation, for example feces continue to be formed and their composition does not differ materially from that of feces passed after an ample diet. Also, a segment of bowel when isolated from the rest of the intestinal tract becomes after a time packed with a mass of pasty fecal material, which of course must be entirely endogenous. Wide variations in the composition of the diet, if the quantity of cellulose remains unaltered, exert little or no influence upon the composition of the feces. The bulk of the feces is reduced however, during starvation, but the reduction is due to the removal of the stimulating effect of the food upon the secretory activity of the intestine. Indigestible materials, especially cellulose, increase the amount of the feces, not only by adding directly to their bulk, but also through increasing the production of endogenous material.

Bacteria constitute ordinarily about 9 per cent

of the total solids of the feces. The nitrogen human feces amounts daily to between 0.5 and gram and, as just mentioned, is largely endogenous. Fecal "fat" is also largely endogenous, continuing to appear in the feces though all fatty material has been excluded from the diet; it differs chemically from ordinary food fat but resembles closely the blood lipids. It consists mainly of lecithin and coprosterol, the latter being derived from cholesterol through the reducing action of bacteria. A certain proportion of the fecal fat is also derived through bacterial action from non-fatty sources. In human feces a part (cholesterol and lecithin) is of biliary origin. Calcium, phosphate, magnesium and other inorganic materials in the feces are also derived mainly from the blood. Fecal iron is mostly exogenous (see p. 59).

The feces owe their color chiefly to *stercobilinogen* (urobilinogen, p. 460) produced by the bacterial reduction of bile pigment; their odor is due to the presence of aromatic substances, chiefly *indole* and *skatole*, derived from the deamination and decarboxylation of tryptophane by bacterial action in the large intestine (p. 508). Thus

Phenylalanine and tyrosine are converted in a similar manner to paracresol and phenol.

Small quantities of indole, skatole and phenol are absorbed into the blood stream but undergo detoxication in the liver by conjugation with sulphuric acid and potassium or with glycuronic acid. Phenol may undergo conjugation in either of these ways; in the former instance phenol sulphate of potassium is formed, in the latter the corresponding glycuronate results. Indole and skatole after absorption are converted to indoxyl which then for the most part combines with sulphuric acid and potassium to form *indoxyl sulphate of potassium* or *indican*, which is excreted in the urine.

Indole and skatole are also conjugated but in relatively small amounts with glycuronic acid

obstruction, e.g., tumor, adhesive bands, strictures somewhere along the bowel, the chief causes are the following:

(1) *Habit*. The act of defecation can usually be readily inhibited by an effort of the will. The refusal to respond to the sensation aroused by a full rectum and the failure to acquire the habit of clearing the bowels regularly at some definite time each day, e.g., after the first meal, is a common cause of constipation. The rectum becomes tolerant, and adapts itself to the increased fecal bulk. (See footnote, p. 504). As a result, the desire to defecate passes. The retention of feces in the distal colon and rectum leads to the excessive absorption of fluid; the feces therefore become dry and hard and less easily expelled. There may at first be no defect in the musculature or movements of the digestive tract as a whole but the lower segment of the colon as a result of continued overloading becomes sluggish. Atony and thinning of the muscular wall may eventually result. To this type of constipation Hurst has applied *dyschezia* (meaning a difficulty in easing oneself). It is obvious then that properly regulated habits are more likely to correct this condition than the use of purgatives which stimulate peristalsis in an intestinal wall that is, in general, in no need of urging. By purgatives "the whole intestinal tract is teased and pained for the defective action of that part of it which is most remote from their influence."

The dyschezia may be aggravated by other factors. Sometimes the angle at the junction of the pelvic colon and rectum is abnormally acute. On the other hand, spasm (or achalasia) of the circular fibers (sphincter) in this situation may be present which offers considerable obstruction to the passage of feces. Weakness of the muscles of the abdominal wall or of the pelvic floor, e.g., the levator ani, may impair the ability of the lower bowel to evacuate its contents.

(2) A *diet* that leaves too little of the necessary residue for the stimulation of intestinal activity or one which contains too little fluid.

(3) A *colon* which absorbs too readily—the "greedy" or "thrifty" colon as it has been called—and causes undue condensation of the intestinal contents.

(4) *Hypertonic state of the musculature of the colon* is a cause of what is termed *spastic constipation*. Both the transverse and descending colons are sometimes held firmly contracted to form a solid cord which may sometimes be felt through the abdominal wall. At other times only the pelvic

5. drugs

and descending colons are affected or again the spasm may be confined to the transverse colon. The contracted bowel is the seat of purposeless spasmodic contractions which have little effect in moving the food onward. The spasticity may be reduced by atropine which acts by depressing the parasympathetic influence upon the large intestine. The hypertonic state supposedly may be induced reflexly through impulses arising in diseased pelvic or abdominal viscera, e.g., the gall-bladder, duodenum or appendix. On the other hand, it may be due to influences of a mental nature, overwork, worry or shock, etc. In the constipation of chronic lead poisoning a spastic state of the colon exists.

(5) *Weakness or depressed activity of the musculature of the colon—atonic constipation.* An inherent defect in the neuromuscular mechanism of the bowel is uncommon. Atony of the intestinal musculature may, however, be associated with certain general conditions, e.g., senility, obesity, etc., constitutional diseases or lesions of the central nervous system. The driving force of the intestinal muscle under such circumstances is subnormal. The delay in the movement of the food may be in the small as well as in the large intestine. A hypotonic state of the intestinal musculature may also result from a diet low in vitamin B₁ (p. 642). Rats fed on diets deficient in inorganic salts show loss of tone and depressed motility of the intestinal tract (Robertson and Doyle). The condition is corrected by adding Ca and K to the diet; which suggests that a low intake of these minerals may be a factor in some cases of chronic constipation in the human subject.

The subjective manifestations of constipation are considered elsewhere (see p. 507).

MEGACOLON—HIRSCHSPRUNG'S DISEASE. This is a relatively rare condition appearing in childhood and characterized by obstinate constipation, tremendous dilatation of the colon and hypertrophy of its wall. The condition is due to an abnormality in the innervation of the colon—an imbalance between the activities of the thoracico-lumbar and sacral outflows. Degeneration of the cells of Auerbach's plexus at the pelvi-rectal sphincter has been described (Cameron). This observation of itself would suggest that the cause of the condition is underactivity of the parasympathetic innervation (motor) rather than overactivity of the sympathetic (inhibitory). According to Hurst, and to Gask and Ross, failure of the pelvi-rectal sphincter or of the internal anal sphincter to relax coordinately with contraction of the colonic wall—*achalasia*—is an important element in the pathogenesis of megacolon (see cardiospasm p. 482). The marked hypertrophy of the

bowel wall seen in some cases supports this view. It is most likely, however, that the imbalance between the sympathetic and parasympathetic innervations is not confined to the sphincters but affects the bowel wall as well. This conclusion is borne out by the fact that the dilated and immobile colon shows strong and effective contractions of the bowel after a spinal anesthetic (fig. 212), an effect which also argues strongly against the view that, in most cases at any rate, the parasympathetic is primarily at fault. It seems to indicate, on the contrary, that the motor mechanism is intact but under the influence of an inordinate inhibitory action exerted through the sympathetic. Furthermore the most successful treatment of the condition consists in excision of the lumbar sympathetic ganglia, or section of the hypogastric (presacral) and inferior mesenteric nerves (p. 502).

INTESTINAL INTOXICATION

THE LARGE INTESTINE

Several substances, some intensely toxic in character, are formed in the large intestine as a result of the decomposition of protein by the normal bacterial flora (colon type of organism). Among such putrefactive products are histamine, phenol, cresol, indole, skatole, ethylamine, isoethylamine, tyramine, etc. (p. 506). Choline is also formed as a result of the decomposition of lecithin and choline gives rise to traces of neurine. Some observers, impressed by the powerful actions of these substances when injected into animals, have suggested that their absorption into the general blood stream is responsible for many ills, and particularly for the well-known symptoms of constipation. Metchnikoff arraigned the colon as the body's greatest enemy. Arbuthnot Lane in more recent times inveighed against this cess-pool and recommended its extirpation under certain circumstances. No reliable evidence can, however, be cited to connect any of the toxic products mentioned with the symptoms of disease. Many of them are produced only in mere traces, and even though some, such as indole, are produced in relatively large amounts (60 mg., according to Herter, may be present in 100 grams of feces), toxic doses are prevented from entering the systemic circulation by the barrier offered by the bowel wall and through the detoxicating action of the liver (p. 507). Indole, for example, when given to the human subject by mouth in an amount (1 gram), which is more than would ever be present in the bowel at one time, produces no symptoms; 2 grams causes only some dizziness and a slight headache, while large amounts may be introduced into the colon without ill effect.

slight absorption of indole and skatole under ordinary circumstances is indicated by the fact that though the feces contain considerable amounts of both these substances, the detoxicated product indican (indoxyl sulphate of potassium, p. 507), may be absent from the urine. On the other hand, the ability of the liver to protect the body against these substances is shown by the observation that large amounts of indican are constantly present in the urine of certain individuals, showing that considerable quantities of the putrefactive products are absorbed, yet such persons enjoy good health.

Choline may be given by mouth with impunity; even when relatively large amounts (15 to 20 mg.

Weiss and associates that in the case of the human subject 20 mg. of histamine may be injected per hour without causing a depressor effect; 500 mg. given orally were inert.

According to Alvarez the symptoms of constipation—headache, furred tongue, foul breath, malaise, etc., are of reflex rather than of toxic origin. Afferent impulses set up from the wall of the overloaded rectum appear to be responsible. Distension of the rectum by inert material such as absorbent cotton has been shown to produce almost all the symptoms of constipation. In the dog, packing the rectum in this way causes a rise of some 10 mm. Hg in blood pressure which is maintained until the foreign material is removed.

FIG. 212. Megacolon. Motor test with spinal anesthesia. Left, the injection of three and one-half quarts of fluid causes painless distension of abdomen. In horizontal position no spontaneous expulsion after fifteen minutes of effort. Right, fifteen minutes after spinal anesthesia. Note the emptying of the lower sigmoid and most of the ascending colon, also the reduction in diameter of the upper sigmoid. (After Scott and Morton.)

per kilo. in the cat) are given intravenously no toxic effects are produced. Since this substance is rapidly destroyed in the blood stream, large amounts may be injected slowly over a period of time without noticeable effect.

Histamine, another powerful depressor substance was found by Meakins and Harington in minute amounts in the cecum, but only insignificant amounts, they conclude, pass through the intestinal wall. Even after the introduction of large amounts into the *small* bowel only slight absorption was evident. Hanke and Koessler gave the amine by mouth in doses of 100 mg. to guinea-pigs; there were no ill effects, and upon analysis of the intestinal contents 24 hours after the administration of this amount, less than 2 mg. were recovered. The chief protection against the toxic effects of histamine is apparently in the bowel wall itself. It has also been found by

The manifestations of constipation referable to the alimentary tract, namely, the loss of appetite, coated tongue and offensive breath are, according to Alvarez, probably due to small waves of contraction originating in the wall of the loaded bowel and traveling in a reverse direction over the small intestine, stomach and esophagus (p. 480). A strong argument against the symptoms of constipation being due to toxic absorption is the almost immediate relief which follows evacuation of the bowels—it would certainly take some time for the blood to be cleared of the poisonous material. Furthermore, in constipation the feces are relatively dry and hard, conditions much less, rather than more favorable to the absorption of putrefactive products. One should expect, indeed, that the latter would occur more readily during diarrhea. Apart from all the indirect evidence against a toxic element being concerned in constipation,

is the positive fact that many subjects of the disorder, even though this is of a severe grade, do not excrete indican in the urine and, as mentioned above, other individuals who for some unknown reason excrete large quantities remain free from symptoms.

There seems little doubt that toxic products of the bacterial flora of the large intestine are prevented from entering the systemic circulation in amounts that are pathologically significant. The microorganisms themselves may however, leave their normal habitat via the lymphatics and locate in the mesenteric lymph-nodes, or may even enter the general circulation.

THE SMALL INTESTINE

The immunity of the body to autointoxication applies only to the large intestine. The small intestine is not equipped in the same degree to resist the passage of toxic products into the blood stream. Normally, however, the bacterial flora of the small intestine are quite different from those of the large. The microorganisms (e.g., *Bacillus bifidus*) in the former situation have a fermentative not a putrefactive action. Through their action upon carbohydrate, organic acids, acetic butyric and lactic, are produced. The acid reaction of the ileal contents is unfavorable to the growth of the proteolytic bacteria. So long as the supply of carbohydrate material is adequate the microorganisms of the acid-producing type flourish and any of the bacteria of the large intestine which may have invaded the small intestine are unable to gain a foothold. Under certain circumstances, however, especially in infants, this does occur. In young children, in whom the protective power of the small intestine is even less than that of adults a severe type of toxemia results, characterized by vomiting, diarrhea, dehydration, acidosis, fever, emaciation and great prostration.

Some believe that guanidine is the toxic product concerned in certain types of intestinal intoxication in infants. In intestinal disorders associated with the extension into the small intestine of the flora of the large, measures are directed toward encouraging the normal acid-producing type of organism in gaining the upper hand. Carbohydrate is supplied, usually in the form of lactose, which passes farther down the intestinal tract than other sugars before it is absorbed. It has also been common practice to administer cultures of the fermentative type of organism, such as that of sour milk—*Bacillus bulgaricus* (so-called as the result of the writings of Metchnikoff who attributed the health and longevity of the Bul-

garian peasant to his drinking large quantities of sour milk). Today cultures of *Bacillus acidophilus*, one of the normal inhabitants of the small intestine, are usually employed. Ordinary *antiseptics* given with the view of inhibiting bacterial growth exert no appreciable effect, although certain sulphonamides are valuable for their bacteriostatic action.

ACUTE INTESTINAL OBSTRUCTION

Symptoms of intense severity result when the lumen of the small bowel is completely obstructed as a result of constriction by an adhesive band, kinking, twisting or pressure by new growth, intussusception, strangulation by a hernial ring etc. The condition is ushered in by severe cramp-like abdominal pain, vomiting and shock. If the condition is not relieved by operation, reverse peristalsis arises above the point of obstruction, intestinal contents pass into the stomach and the vomiting becomes fecal in character. Later the bowel above the obstruction loses its tone, becoming dilated and filled with intestinal secretion and gas. The loss of fluid in the vomitus and the drainage of large quantities of fluid into the distended bowel leads to a *fall in blood chloride alkalosis* and *dehydration* (p. 17). Other blood changes are a *rise in the non-protein nitrogen* and an *increase in the fibrinogen content*. The former is the result of tissue destruction combined with impairment of renal function. Great prostration occurs, ending in death.

Functional obstruction. The dilated, immobile state of the bowel described above as occurring in the later stages of a mechanical obstruction occurs from other causes and is then referred to as *paralytic* or *adynamic ileus*. The most common cause of paralytic ileus is peritonitis; it may also result from some severe intestinal injury or undue handling and exposure of the bowel during abdominal operations. The distended bowel is incapable of propelling the feces along its lumen that is, obstruction of a functional character exists. When the bowel above a mechanical obstruction has become atonic and dilated, functional obstruction tends to persist after the mechanical block has been relieved by operation. For this reason late operations for the relief of acute intestinal obstruction are attended by very high mortality.

EXPERIMENTAL OBSTRUCTION

When the intestine of an animal is tied across the symptoms which follow are chiefly weakness, prostration and vomiting. The animal shows

little or no evidence that it is suffering pain. The higher in the intestinal tract that the obstruction is made, the more severe are the symptoms, and the shorter is the duration of life after the operation. Following obstruction of the colon the animal may survive for some weeks, whereas after obstruction of the jejunum or duodenum it dies as a rule within five or six days. Reduction in blood volume (anhydremia); fall in blood chloride (see below); increased alkali reserve and non-protein nitrogen of the blood, and a rise in the percentage of fibrinogen occur.

Paralytic ileus may be produced in dogs by the injection of a solution of iodine into the peritoneal cavity. It was shown by Campbell and Markowitz that the intestinal inhibition produced in this way could be abolished by spinal anesthesia which apparently blocked inhibitory impulses reaching the bowel through the splanchnic nerves (p. 502).

A CONSIDERATION OF THE CAUSE OF DEATH IN MECHANICAL OBSTRUCTION

A number of theories have been advanced in recent years in attempts to give an explanation for the symptoms and death in acute mechanical obstruction of the bowel. We may, at the outset, dismiss the possibility that death is simply the result of blockage of the alimentary tract, and the prevention of the passage of food along its lumen. It was shown originally by Stone, Bernheim and Whipple that if a few inches of the bowel were excised, both ends of the segment closed and the continuity of the digestive tract then re-established by an anastomosis of the cut ends of the bowel, death occurred even more rapidly than if the bowel had been obstructed by ligation. The survival time after the closure of such an isolated segment or loop is rarely more than 3 or 4 days and may be only 24 hours.

Toxic theories

A bacterial theory in one or other of its modifications has had its adherents. The toxin of the Welch bacillus has been suspected by some, but little support has been given by recent work to the belief that this or any other bacterial toxin is responsible for the symptoms. Others have thought that a toxic agent derived from the bacterial decomposition of protein within the intestinal lumen was the lethal agent. Histamine, in particular, has been mentioned in this connection. Though the increased excretion of ethereal sulphates (p. 551) which occurs in intestinal obstruction indicates that putrefactive products

are absorbed into the blood stream in larger amounts than usual, all the evidence is against histamine or any other of these substances playing a leading rôle in intestinal obstruction (see also p. 508). It is impossible to consider seriously any bacterial theory of intestinal obstruction, for such theories ignore the fact that the symptoms diminish in intensity, and the survival time is lengthened, the lower in the intestinal tract that the obstruction is produced. Bacterial growth, protein decomposition and histamine concentration on the other hand, are all greater in the lower than in the higher reaches of the intestinal tract.

Whipple and his associates obtained a substance which they believed to be a *proteose* from the mucosa of the obstructed bowel; normal bowel did not yield it. When injected intravenously into normal animals, the material proved to be intensely toxic, producing symptoms similar to those of intestinal obstruction. It was quite innocuous, however, when given by mouth, or when introduced directly into the bowel. These workers, therefore, concluded that death in acute obstruction was due to a toxemia—the absorption of a toxic proteose formed in the mucosa of the obstructed bowel. There has been no confirmation of this theory by more recent work.

The dechlorination and dehydration theory

It was first shown by Hartwell and Hoguet (1912) that obstructed animals which survived for some days showed marked dehydration. Vomiting, it was claimed, was responsible for the reduction in body water; the symptoms of obstruction and death were believed to be the direct consequence of the dehydrated state. They showed, and their observation was confirmed by Haden and Orr and others, that the life of an animal with an obstructed intestine could be prolonged by the subcutaneous or intravenous administration of saline.

That the loss of chloride in the vomitus may cause a profound fall in blood chloride, and dehydration is an established fact. Hastings, Murray and Murray found that in dogs, obstruction at the pylorus caused a reduction in the blood chloride to 50 per cent of the normal within a few days after the operation. Gamble and Ross confirmed this observation and made a more extended study of the changes in blood chemistry which follow pyloric obstruction. They consider that loss of chloride, by leading to a reduction in the electrolytes of the body, is the primary cause of the dehydration. They state that "a withdrawal of the electrolytes of the body fluids will be accompanied by a proportionate reduction in

the volume of body water and that this change can only be repaired by replacing both the lost water and the lost electrolytes," that is, the volume of body fluid is sustained by its content in total electrolytes. These observers showed that the loss of chloride in the vomitus is repaired for a time by the retention of carbon dioxide and the consequent increase in bicarbonate. By this means the concentration of electrolytes is maintained. In other words, the sum of (Cl^-) and (HCO_3^-) remains constant for a time (30 hours or so) after the obstruction has been established. A degree of alkalosis, however, results, which is countered by a loss of base (Na) in the urine; a reduction in (Cl^-) + (HCO_3^-) occurs. The

FIG. 213. Diagram to show change in the total content and distribution of electrolytes in the body fluids following pyloric obstruction. (After Gamble and Ross.)

reduction in ionic concentration of body fluids resulting from the depletion of base, which unlike Cl^- cannot be substituted for, is accompanied by a proportionate loss of water (fig. 213). These observers state that the value of sodium chloride injections in prolonging life in obstructed animals depends upon the fact that the replenishment of the stores of sodium permits the retention of water. Chlorides such as NH_4Cl or KCl are without any beneficial effect, nor will water alone or a solution of glucose prolong life.

The reduction in the blood chloride is not necessarily the result of vomiting. The accumulation of secretions above the point of obstruction will just as surely cause chloride depletion and dehydration. In the rabbit for example, which

cannot vomit, obstruction causes the characteristic blood changes. A most powerful stimulant to secretion is distension of the bowel wall; the dilated bowel in the later stages of obstruction thus becomes a receptacle for large quantities of fluid. In the case of the rabbit, fluid amounting to thirteen per cent or so of the body weight may be found in the stomach and bowel after death. The fatal effect of distension has been shown by Herrin and Meek. They distended a loop of bowel by means of a balloon and allowed the continuous secretion which resulted to drain to the exterior. The animals died in from 6 to 14 days. A loop of bowel opening to the exterior but not distended causes no injurious effect. Herrin and Meek concluded that the loss of chloride in the secretion was the essential factor leading to the death of their animals. Dragstedt and Ellis have also shown that the profound fall in blood chloride which follows the drainage of the gastric juice to the exterior is accompanied by grave symptoms and ultimately ends in death. The symptoms are rapidly relieved by the administration of saline. Fine and his associates have reported pronounced reduction in the plasma volume of patients suffering from acute obstruction of the small intestine.

There is no doubt that chloride loss and dehydration are important factors in the *later* stage of obstruction. The administration of saline is one of the most valuable measures possessed by the clinician for combating the condition at this stage either before or following operation.

Nevertheless, though the blood changes at this time undoubtedly prejudice the animal's chance of survival, it is unlikely that they play the primary rôle in causing death. For one thing, correction of the blood chemistry though it prolongs life is not curative. Moreover, death frequently occurs before any significant change in the blood chlorides takes place, while on the other hand, the blood chloride may be maintained at a level considerably lower than that usually seen in obstruction without the animal becoming moribund. The following experiments* indicate a nerve element as the primary cause of the train of symptoms seen in acute obstruction. A balloon was placed in the lower duodenum and distended to a pressure of about 100 mm. Hg. A large sized rubber tube attached to the balloon prevented any actual obstruction. X-ray examination showed that a barium mixture moved freely beyond the distended region. These animals

* Taylor, Weld and Harrison.

had symptoms indistinguishable from acute obstruction yet little fluid was lost by vomiting and the blood chlorides showed practically no change. On the other hand, otherwise normal animals who had had the blood chloride depleted by means of histamine injections (to stimulate gastric secretion) and apomorphine (to induce vomiting) remained in apparent good health even though the blood chloride had been maintained at a level 50 per cent below the normal for three weeks.

It is evident that in the balloon experiments just mentioned, distension of the bowel caused death in some way other than by chloride depletion. Another group of animals in which the bowel was distended by a balloon as described, but in which the segment of bowel had been first denervated survived for a much longer time than those in which a preliminary denervation had not been performed. This result indicates that afferent impulses arising from the distended segment of bowel are concerned in some way with the severe symptoms of obstruction. Herrin and Meek also observed that if a distended draining loop were denervated the animals survived indefinitely. They, however, offer an explanation of the benefit derived from denervation based upon the theory that dechlorination plays the essential rôle, namely, that when the vomiting and loss of appetite produced reflexly from the distended loop are abolished by nerve section, chloride loss is reduced and chloride ingestion increased. The importance of afferent impulses from the intestine in the production of the symptoms of obstruction therefore must be admitted; that they may cause death quite independently of dechlorination is evidenced from the experiments described in the last paragraph. It is well known that many reflex effects upon the cardio-vascular system and upon several important functions can be initiated from the gastro-intestinal tract. The

severe pain and collapse which result from the distension of other hollow viscera, e.g., the gall-bladder, stomach, kidney pelvis, etc., may also be recalled in this connection. Moreover, the severe symptoms and early death which result from the mere distension of the bowel by a balloon calls to mind the analogous clinical condition known as Richter's hernia. In this condition only a portion of the intestinal lumen is pinched off and isolated from the main passage. The bowel is not obstructed, yet all the symptoms of acute obstruction are present. It is quite conceivable that acute distension of the small isolated pocket by secretions and gas is responsible for the symptoms.

The contention of Zwemer and his associates that a high level of blood potassium is the cause of death in intestinal obstruction has not been substantiated by others. Keith and Binger, for example, raised the blood potassium of a group of normal persons and observed no harmful effects, and in patients suffering from obstruction there is a tendency for the potassium concentration of the blood to decrease rather than to increase (Falconer). In experiments with dogs Greenwood, Haist and Taylor found a significant rise in potassium as a terminal event only, and concluded, therefore, that hyperpotassemia was a factor of little importance as a cause of death in intestinal obstruction.

The importance of distension as a factor in acute obstruction of the intestine is now generally recognized and it has become the practice in suitable cases to decompress the bowel by suction-drainage through a tube passed from the mouth to the duodenum (Wagenteen and Paine) or, as in the method of Miller and Abbott, to insert a long slender tube through the nose into the stomach and allow it to be carried to the level of the obstruction. The tube has a double lumen and is provided at its tip with a small balloon which can be inflated after it has entered the duodenum. The balloon serves as a stimulus to peristalsis which carries it and the tubing along the bowel to the point of obstruction.

CHAPTER XLV

VISCERAL SENSATIONS

The abdominal and thoracic viscera are insensitive to the several types of stimuli which readily arouse sensations in the skin and more superficial tissues of the body. The effects of the different varieties of stimulus—*thermal, chemical, tactile* and *pain*—have been investigated by a number of observers including Ross, Head, Mackenzie, Hurst and Carlson.

Sensations of pain cannot be elicited from the viscera by the usual means. The intestine or the liver, the stomach or the heart may be cut, burned or pinched without arousing any immediate sensation. In the second stage of a colostomy operation, for example, the colon can be opened without pain being experienced by the patient. Harvey remarked upon the absence of sensation in the exposed heart of Viscount Montgomery.¹

The insensibility of the alimentary tract to ordinary forms of stimulation commences in the lower or middle third of the esophagus and extends as far as the commencement of the anal canal. How can these observations be reconciled with the well-known fact that pain is one of the commonest manifestations of visceral disease?

The whole subject of pain arising in or referred from the viscera is still of a highly controversial nature. No final answer can be given. The most that can be attempted is a summary of some of the more significant experimental results and clinical observations, and the opinions of those who have especially interested themselves in the subject.

Lenander considered that abdominal pain was always due to the stimulation of somatic nerve terminals in the parietal peritoneum or mesentery; the bowel itself was supposed to be quite devoid of pain fibers. According to this view therefore, pain localized within the organ itself—*true visceral pain*—was an impossibility.

Ross's theory postulated that visceral pain was

of two types: (a) *referred pain*, and (b) *visceral* or *splanchnic pain*, which was distributed poorly localized and arose in the viscus itself.

Mackenzie, as a result of his clinical observations strongly supported Ross's idea of referred pain, but maintained that *all* visceral pain of this nature, the viscera being quite insensitive to all forms of stimulation. In agreement with Lenander, he did not believe that the viscera contained pain fibers, true visceral pain was therefore never experienced.

Mackenzie's conception of referred pain

When a viscus is diseased, pain or tenderness is frequently felt in the tissues overlying it approximately (abdominal or chest wall) or in some quite remote from it. For example, pain is felt in the neck or shoulder (fig. 214) in conditions affecting the diaphragm, between the scapulae in gastric disease, or in the region of the umbilicus in appendicitis over the precordium or in the arm in angina pectoris (p. 280). When traction is made upon a coronary artery of a dog, the animal whines and indicates the location of the pain by limping on the left fore-paw. Other examples are, the pain in the perineum and tip of the penis caused by a stone in the region of the neck of the bladder, and the pain in the groin due to a stone in the ureter.

It will be recalled (p. 848) that a given segment supplies a visceral area with autonomic nerve fibers and a well-delineated area of the body (dermatome) with somatic nerves. The two areas of structure linked in this way through the spinal cord may be some distance apart (e.g., diaphragm and shoulder) or be more closely related (e.g., abdominal wall and an underlying abdominal viscus). Mackenzie believed that afferent autonomic impulses arising in a diseased organ, though of themselves incapable of arousing any sensation, would upon entering the cord set up an "irritation focus" with the result that cells accustomed to receive impulses from the corresponding somatic area were excited. Thus, the impulses from the viscera "irradiated" on to cells of the corresponding somatic center. New impulses originating in these cells travelled along the usual pathways to higher perceptive centers (thalamus) which

¹ Harvey records, "I carried the young man to the King (Charles I) that His Majesty might with his own eyes behold this wonderful case, that, in a man alive and well, he might, without detriment to the individual, observe the movement of the heart, and with his proper hand even touch the ventricles as they contracted. And His Most Excellent Majesty, as well as myself, acknowledged that the heart was without the sense of touch, for the youth never knew when we touched his heart."

ected or referred the sensation to the somatic area e.g., skin or muscle, from which it was accustomed to receive impulses. In this way, spontaneous pain in superficial structures remote from the diseased site was accounted for. Mackenzie spoke of these reactions as *viscero-sensory reflexes*." Tenderness to touch, pressure or light pinching of the skin (hyperesthesia and hyper-

indicating the referred nature of the pain. He explained the rigidity (hypertonus) of muscles overlying a diseased organ, the right rectus abdominis in acute appendicitis, for example, upon a similar basis. Afferent impulses of normal intensity arising in the muscle proprioceptors upon arriving at the spinal centers, which had been rendered hyperexcitable by the receipt of abnormal visceral impulses, resulted in a reflex increase in tonus of the corresponding muscles.

FIG. 214. Location of maximum points of referred pain from diaphragm irritation in twenty-three cases. They are all situated in the region supplied by the third and fourth spinal segments. (After Capps.)

esthesia) was ascribed to the impulses, which primarily would be below the threshold for pain, arriving in the segment rendered hyperexcitable as a result of impulses received from the diseased organ. In the case of the abdominal viscera, Mackenzie claimed that the area of tenderness in the abdominal wall remained fixed, though the position of the diseased organ changed, thus

TABLE 37*

VISCUS	SPINAL SEGMENTS
Lungs.....	1-7 dorsal, mostly 2-5 dorsal
Heart.....	3-5 cervical, 1-8 dorsal, predominantly on left side, sometimes bilateral
Esophagus.....	Mainly 5 dorsal, also 6, 7 and 8 dorsal
Breast.....	4 and 5 dorsal
Stomach.....	7, 8 and 9 dorsal, usually bilateral
Intestine.....	9-12 dorsal, bilateral or on left side only
Liver.....	8-10 dorsal on right side
Gall bladder....	Mostly 8 and 9 dorsal, also 5-7
Kidney.....	Mostly 10 dorsal, also 11 and 12 dorsal and 1 lumbar
Ureter.....	11 and 12 dorsal and 1 lumbar
Testis.....	10 dorsal
Epididymis....	11 and 12 dorsal
Bladder.....	11 and 12 dorsal and 1 lumbar, also 3 and 4 sacral
Prostate.....	10 and 11 dorsal, also 1-3 and 5 sacral
Ovary.....	10 dorsal
Fallopian tubes..	11 and 12 dorsal
Uterine cervix..	11 and 12 dorsal and 1-4 sacral
Uterine body....	10 dorsal to 1 lumbar

* From W. R. Brain, Diseases of the Nervous System, after Head.

The referred motor reaction he spoke of as a *viscero-motor reflex* (see fig. 215).

The conception of referred pain was supported by the work of Head, who mapped out the segmental distribution of the cutaneous nerves responsible for hyperesthesia in diseased states. This theory has gained wide acceptance.

In table 37 are given the segmental areas to which pain is referred in disease of various viscera (Head).

True visceral pain

True visceral pain, though denied by Mackenzie, exists. The pains of childbirth, for example, or

the pain of intestinal colic or of an over-distended bladder are undoubtedly felt in the organs themselves. Also in transection of the cord resulting in complete paralysis and anesthesia of the abdominal wall intestinal pain is experienced, which obviously cannot be due to reference to somatic nerves. Impulses in such cases must have reached the central nervous system along intact visceral (autonomic) afferents and either have entered the cord by the posterior roots above the point of transection or have been conveyed by the vagus. It has not been definitely demonstrated that the sensation of pain can be conveyed by the

many disease of the appendix. A distinction should be drawn between pain of this nature and referred pain.

The adequate stimulus for visceral pain

The existence of true visceral pain is not incompatible with the statement made above that the viscera are insensitive to the ordinary type of stimulus. Hurst's experiments indicate that the only adequate stimulus for visceral pain fibers is tension. Distension of a hollow viscus e.g., stomach, intestine, gall-bladder, etc., give rise to pain as a result of the stretch stimulus applied to the nerve terminals in its wall. The pain may be either roughly localized to the viscus itself, or referred.

Though the question is by no means settled, it appears that contraction of the muscular wall of a hollow viscus does not of itself give rise to pain. Pain arises, however, if the contraction causes distension of a neighboring portion of the wall as may result when the contraction wave approaches a mechanical obstruction, a length of bowel in spasm or a sphincter which fails to relax (*achalasia*). Poulton, for example, found that when a balloon was inserted into the lower part of the human esophagus, the approach of a peristaltic wave toward the obstruction caused pain, but during its passage over the esophageal wall in contact with the balloon no sensation was felt. Poulton attributes the absence of pain during the passage of the contraction wave to the reduction in the diameter of the tube and the consequent relief from stretch of the nerve endings lying between the muscle fibers. Pain also ceased if the esophageal muscle relaxed to accommodate the balloon; that is, adjusted the length of its fibers to the distending force (postural tone, see p. 47). As further evidence for the effectiveness of distension in causing pain, the following observations may be cited. In animals, when an intestinal loop exposed under local anesthesia is stimulated to powerful contraction, there is no evidence of pain, whereas even moderate distension of the loop (as by inflating it with a balloon) is manifestly painful. Distension of the gall-bladder of the cat is accompanied by reactions indicative of intense pain. Distension of the human appendix by the injection of fluid through an appendicostomy opening causes severe pain in the epigastrium or in the region of the umbilicus and when the duodenum is distended by the injection of material through a duodenal tube, pain is felt on the right side. The pain impulses

FIG. 215. Diagram to illustrate Mackenzie's theory of referred pain. A, representing normal conditions, a visceral reflex is shown. B, illustrates a visceromotor and a viscerosensory reflex. Impulses from a viscus are conceived as setting up an irritable focus in the cord which through the involvement of neighboring neurons increases the tone of muscles innervated by the same segment, and causes a discharge of impulses over the pathway for pain. The sensation is then projected in consciousness to the periphery, as indicated by the dotted line.

afferent fibers of the vagus, but it is possible if not probable that such is the case. Pain arising in the viscera is diffuse, poorly localized and often of a dull, boring character. These features are characteristic of protopathic sensibility in general, and the viscera apparently are supplied only with fibers capable of conveying this type of sensation. The impulses responsible for this primitive type of sensation are believed to ascend no higher than the thalamus (p. 880).

Pain in a normal viscus may result from disease in a distant organ through a visceromotor reflex. Painful pylorospasm, for example, may accom-

doubtedly reach the central nervous system through the splanchnic nerves. Bentley and Smithwich distended the duodenum of patients whose splanchnics had been divided on one or on both sides. After unilateral denervation, distension caused pain on the denervated side only; no pain whatever was felt after bilateral splanchnic section.

Morley's theory of abdominal pain

Morley contends that the referred pain of abdominal disease does *not involve autonomic afferents* as postulated by Mackenzie but is due to the stimulation of *somatic* pain fibers in the parietal peritoneum or mesentery, the sensation being referred to the superficial area innervated from the same segment. He expresses what he terms the *law of referred pain* in the following words. *Referred pain only arises from irritation of nerves which are sensitive to those stimuli that produce pain when applied to the surface of the body.* He believes that the somatic innervation of the peritoneum extends along the mesentery to within a short distance of its attachment to the bowel and does not terminate as has been generally supposed near the root of the mesentery.² The mesentery or peritoneum is therefore sensitive to tearing, cutting, etc., whereas the organ itself which contains only autonomic afferents is insensitive to these types of stimulus. In support of his views Morley cites the pain in the shoulder associated with irritation of the peritoneal covering of the diaphragm. He points out that the diaphragm is innervated (through the phrenic) chiefly by the fourth cervical spinal segment and to a less extent by the third and fifth. None of these segments give rise to autonomic fibers but the third and fourth cervical nerves furnish somatic afferent fibers to the shoulder area in which the referred pain of diaphragmatic disease is located. Morley explains muscular rigidity in a similar manner—the radiation of impulses over motor nerves. He replaces Mackenzie's terms, viscerosensory and visceromotor reflexes by *peritoneo-cutaneous ra-*

diation and peritoneo-muscular radiation respectively. Morley also recognizes true visceral pain resulting from an adequate stimulus—, namely, tension. The pain and tenderness resulting from pressure upon an inflamed viscus (e.g., ulcer of the duodenum) through the abdominal wall he ascribes however, to the parietal peritoneum being brought into contact with the roughened surface of the lesion. As evidence that the sensation is not, in such instances, referred to the skin from the diseased structure, but is due to the stimulation of nerves in the parietal peritoneum he states that (a) the area of tenderness shifts with the movement of the viscus, (b) the tenderness is not abolished by infiltration of the skin with novocaine, and (c) direct pressure upon the inflamed organ when exposed by operation in a conscious patient (i.e., under local anesthesia) does not give rise to any sensation. Morley has made out a case for the production of pain in some instances through a peritoneo-cutaneous reaction, and for pain and tenderness upon pressure being the result of the stimulation of somatic nerves in the parietal peritoneum. Nevertheless, it is probable that referred pain in other instances is brought about through the mediation of both visceral and somatic nerves (viscero-sensory reflexes). Woollard and Carmichael, for example, have obtained evidence for the latter from experiments upon the human testis which, since it has migrated from the abdominal cavity and is enveloped by peritoneum, may be looked upon as an abdominal organ, in so far as the question of referred pain is concerned. These observers found that after all the nerves to the testis had been blocked by means of novocaine, except the autonomic fibers passing along the spermatic artery, no sensation was felt within the organ when it was compressed; but pain, referred to the tenth dorsal segment—lower abdomen and back—was experienced. Moreover, pain is unquestionably referred from the heart (e.g., in angina pectoris) to the left arm and from the biliary tract to the inter or subscapular region.

An explanation of referred pain on the basis of reflex vasomotor changes or the liberation of a chemical substance at somatic nerve endings

Pollock and Davis stimulated the peritoneal surface of the diaphragm in dogs. The animals showed every sign of suffering pain, which was abolished by any one of the following procedures. Section of the phrenic nerve; removal of the cervical sympathetic chains; severing the eighth cer-

² Sheehan has made a study of the nerves of the mesentery and finds the following types of fiber:

(1) Fibers ending in Pacinian corpuscles scattered throughout the mesentery. These are afferent sympathetic fibers which travel in the splanchnic nerves.

(2) Free non-myelinated fibers. These are afferent and efferent sympathetic fibers; their terminals are distributed to the serous covering of the bowel. They provide a medium for the transmission of true visceral pain.

(3) Free myelinated fibers derived presumably from somatic nerves. These apparently do not extend as far as the serous covering of the bowel itself.

vical and the first, second and third thoracic anterior roots; transection of the cord at the seventh cervical segment; destroying the cord at the first and second dorsal segments; or section of the cervical posterior roots. Pollock and Davis conclude from these results that the pain impulses following stimulation of the diaphragm travel over the phrenic, enter the cord by the posterior cervical roots, descend the cord to the level of the eighth cervical and first, second and third thoracic segments. Connections are then made with cells in the lateral horn of gray matter (intermediolateral column) from where impulses pass by sympathetic preganglionic fibers to the cervical sympathetic chain, and then by postganglionic fibers "to the skin, blood vessels, meninges and other structures, where by some vasomotor (?) or hormonal (?) process the sensory endings of the cerebro-spinal system are stimulated and a sensory impulse travels over the ordinary cerebro-spinal system, enters the spinal cord by the posterior roots and ascends to consciousness."

The experiments of Lewis and Kellgren

Lewis and Kellgren agree with Lenander, Mackenzie and Morley that the bowel itself is not innervated by fibers mediating the sensation of pain. They argue that did such fibers exist they should give rise to pain when stimulated in other ways than by tension, such as by cutting, pinching or burning. In support of this view, they point out that though light waves constitute the adequate stimulus for the visual receptors, the fibers of the optic nerve respond to mechanical stimulation, such as cutting, by a flash of light (see p. 959). It is claimed that the pain caused by contraction or distension of the bowel is due to traction upon the mesentery and the stimulation of the pain fibers contained therein.

These investigators have carried out experiments upon a number of human subjects; their results are highly significant to the question of referred pain. Pain closely resembling in character the referred pain of visceral disease was induced by the injection of a small quantity (0.3 cc.) of hypertonic saline into an interspinous ligament at various spinous levels. Injection into the 1st lumbar interspinous ligament caused pain distributed in a manner strikingly similar to the pain of renal colic, namely, in the loin and in the inguinal and scotal regions. The pain was accompanied by retraction of the testis. Injection into the 9th thoracic interspinous ligament caused pain in the back in the region of the 1st lumbar spine and over an area in front extending from the 9th costal cartilage on the affected side to the umbilicus. Rigidity of the ab-

dominal muscles and deep tenderness were associated with the pain. Stimulation of the 8th cervical ligament was followed by pain in the interscapular region, over the pectoralis major muscle and down the inner side of the elbow and forearm, together with a sensation of constriction in the upper part of the chest on the stimulated side. Several subjects of angina pectoris were chosen for experiment and were asked to compare the pain which they experienced in an attack with that caused by the stimulation of the 7th cervical or the 1st thoracic interspinous ligament. In all instances the patients described the experimentally induced pain as being identical in character with that caused by the disease, though it showed some minor differences in distribution.

Lewis and Kellgren also found that in cats mechanical stimulation (pinching) of the pancreas or of the mesentery in the duodenal loop, caused motor reflexes from the abdominal muscles which resembled closely those caused by stimulation of the back muscles. The muscular responses were abolished by section of the splanchnic nerves.

Lewis and Kellgren have drawn the conclusion from their results that the pain of visceral disease and the pain arising in deep somatic structures, i.e., all deep-seated pain, is mediated by a common system of nerves. In their opinion there is no physiological justification for placing visceral pain in a special category. Though one pain is mediated by fibers which have their endings in the mesentery and omentum and travel with sympathetic efferents (see page 942), and the other by fibers which terminate in somatic structures, both enter the central nervous system by the posterior nerve roots, and there is no indication that their courses within the cord or their central terminations are not identical. So-called referred pain, they suggest, is simply a matter of localization, which is precise in superficial structures, innervated by one part of a spinal segment, but more diffuse and inaccurately localized in deep structures innervated by another part of the same segment. It is this diffuse type of pain which has been called "referred." Thus, they maintain, there is no necessity to postulate an irritable focus in the cord through which a somatic and a visceral system of nerves are linked.

THE SENSIBILITY OF THE ALIMENTARY TRACT TO TACTILE, THERMAL AND CHEMICAL STIMULATION

Touch. The sensation of touch disappears at the lower end of the pharynx. This was shown by Hurst by means of an esophageal tube with a slit on one side through which the mucosa of the esophagus could be stimulated. Carlson, by means of a test-tube brush passed into the stomach, was unable to elicit the sensa-

tion of touch from the gastric mucosa. The rectum possesses no tactile sensibility but the anal canal is sensitive.

Thermal sensibility. The esophagus is sensitive to extremes of heat and cold. The sensations of temperature that are felt when hot or cold materials enter the stomach have been thought by some to originate in the lower end of the esophagus, by others to arise in the skin of the epigastrium, either through thermal conduction or by reflex changes in the cutaneous blood vessels. Carlson has shown, however, that the gastric mucosa is sensitive to extreme temperature changes, i.e., protopathic thermal sensibility (below 13°C. or above 45°C.). It is the lower end of the esophagus, however, which is responsible for the greater part of the thermal sensation that is experienced when excessively hot or cold materials are swallowed. This is due to the greater sensitivity of the esophageal mucosa, as well as to the fact that the material is retained for an appreciable length of time above the cardia. The colon is insensitive to temperature changes, but even comparatively slight differences in temperature can be detected in the anal canal.

Chemicals, with the exception of alcohol, cause no sensation whatever when introduced into the stomach or intestinal canal. The mucosa is completely insensitive to acids; the introduction into the healthy stomach of a solution of 0.5 per cent hydrochloric acid causes no pain or sensation of any kind. Alcohol stimulates the mucosa of the esophagus and stomach and causes a sensation of warmth. Peppermint and various condiments free from alcohol arouse no sensation. The pelvic colon and rectum show a similar sensitivity to alcohol but are insensitive to other chemicals. The anal canal is extremely sensitive especially to alcohol and glycerine. Both cause a burning sensation.

NAUSEA

Nausea usually precedes the act of vomiting (p. 490) but may occur alone. On the other hand vomiting may occur without nausea, as in certain cerebral conditions. The sensation is felt in the back of the throat or pit of the stomach, and in its milder degrees is merely a "sinking" sensation in the epigastrium. It is frequently associated with vasomotor disturbances and sweating. Increased tension upon the walls of the stomach or duodenum is a potent cause of the sensation, and Poulton has shown that it is also induced by distension of the lower part of the esophagus. During the passage of a peristaltic wave which relieves the tension upon the nerve fibers (p. 516) in the esophageal walls the sensation is relieved. Barclay showed by radioscopy in the human subject that nauseous odors caused the lower border of the stomach to descend an inch or two evidently as a result of sudden relaxation of the abdominal

muscles. This movement would tend to stretch the esophagus and gastric walls and so exert tension upon the nerve endings. The stimulus which induces nausea is, therefore, the same, apparently, as that which causes visceral pain, but of lower intensity. It is likely that the sensations experienced during changes in speed of an elevator is also the result of tension exerted upon the esophagus and gastric walls. This element is also probably a contributory factor in the production of sea sickness, being brought into play by the pitch and roll of the ship (p. 493).

The relief of nausea and vomiting by the application of counter irritants to the epigastrium or over the sternum is probably due to either a reflex change in the postural tone of the gastric walls or to the reflex initiation of peristaltic contractions (p. 516). The tension upon the nerve endings in the latter instance is taken up by the muscle fibers. Poulton observed, for example, that the sensations caused by a balloon in the esophagus were relieved by vigorous friction of the skin over the sternum; contraction of the esophagus in some cases or adjustment of the postural tone of the esophageal wall in others were observed to accompany the disappearance of the sensation.

HUNGER AND APPETITE

Since these sensations are so frequently associated they tend to be confused in consciousness and it is often difficult to separate them clearly. The two are, however, essentially different, and appetite is not merely a less intense degree of hunger. The sensation of appetite may be experienced when the stomach contains plenty of food, and is therefore quite independent of hunger. On the other hand, though hunger is usually accompanied by keen appetite, this is not necessarily so. It is well known that the appetite may be lost though a feeling of emptiness and hunger be present. The two sensations also differ in that one (hunger) is unpleasant, while the other is pleasant (Ryle).

Hunger is a gastric sensation and is due to the strong peristaltic contractions that arise in the stomach when it is empty or nearly so (p. 493). These may cause a sense of discomfort or actual pain—the pangs of hunger. The normal sensation of hunger is believed to be a purely local one, arising in the gastric region, and is not directly dependent upon the state of the blood or any state of the general tissues of the body. The local nature of the hunger sensation is evidenced by several observations. Cannon and Washburn showed clearly the relation of the contractions of

the empty stomach to the sensation of hunger. The following facts indicate that hunger is not due to a general bodily state. It is aroused while the intestine still contains plenty of unabsorbed food, and becomes less intense in prolonged periods of starvation. Filling the stomach with bulky material that possesses little nutritive value, or is indeed totally inedible, inhibits the contractions characteristic of the empty organ, relieves the pangs of hunger and may even create a feeling of satisfaction. This fact has some practical bearing in the treatment of obesity, since the subject may satisfy himself with foods such as salads, fruits, etc., possessing large volume relative to their caloric values.

Though the importance of the gastric element in the production of hunger cannot be denied, the occurrence of this sensation has been reported after complete gastrectomy. Afferent impulses from the duodenum were probably responsible in these instances; they likely play a part also under normal circumstances. The sensation of emptiness which is frequently associated with "rumblings" (borborygmi) in the small bowel, is also probably of intestinal rather than of gastric origin.

Appetite, on account of its complex nature and vague localization, is a more difficult sensation to define; some persons refer it to the pharynx or esophagus, others to the stomach. It is probably to a large degree acquired rather than inborn like the hunger sensation. That is to say, it is dependent upon previous experience; and conditioned stimuli (p. 907) enter largely into its causation. A new-born infant experiences hunger but probably not appetite. Nevertheless, it appears that there is also a purely gastric element in the production of appetite. For example, alcohol, by stimulating the gastric mucosa, causes a sensation of warmth within the stomach, raises gastric tone and arouses appetite. According to Carlson hydrochloric acid does likewise, and the flow of gastric juice induced by the taste of food may well serve the purpose of augmenting the appetite in the initial stage of digestion. It is well known that appetite is often greatly increased after the first few mouthfuls have entered the stomach, and though the effect produced by the taste of the food is difficult to exclude, the fact points to a gastric element. Pavlov has reported, as his own experience, the pronounced effect which a glass of wine, after reaching the stomach, had in restoring the lost appetite following an illness. There is also some evidence that impulses arising not only from the mucosa but from the deeper

structures of the gastric walls play a part and that increased muscular tone is a factor in the production of appetite. The smell of a disgusting material may, as we have seen (p. 519) cause a sudden lowering in the position of the stomach, an increased tension to be exerted upon its walls, and a sensation of nausea—the antithesis of appetite. Conversely an increase in the tone of the gastric muscle, by reducing the stretch upon the nerve terminations of the stomach wall, would conceivably be conducive to gastric comfort and well-being, leading to the appetite sensation. In fasting the gastric tone is also high and this may well be the cause of the keen appetite usually associated with hunger; the latter, on the other hand, as stated above, may be ascribed more particularly to the rhythmic contractions. Support for the conception that gastric tone is an important factor in the production of appetite is offered by X-ray examination of the stomach in various conditions associated with disorders of appetite. In those diseases in which a poor appetite is a prominent feature the gastric tone is low, and in others characterized by excessive appetite, the stomach is very frequently hypertonic. The association of loss of appetite and gastro-intestinal hypotonicity in B_{12} deficiency (p. 642) may also be recalled in this connection. Barclay has recorded experiments upon hospital patients in whom the sight or smell of appetizing food was responded to by an increase in gastric tone. In some the mere suggestion of a glass of beer was sufficient to bring this about. On the other hand, mental states, e.g., anxiety, worry, fear, etc., which lower gastric tone, also depress the appetite. The probability of appetite having its origin, in part at least, in the walls of the stomach is indicated by what Ryle considers a very significant fact, namely, that in diffuse carcinoma of the stomach ("leather bottle" stomach) loss of appetite is a prominent and almost constant symptom. In other diffuse types of gastric carcinoma, even though far advanced, the appetite may be retained. Bitters and other so-called appetizers unless made with alcohol exert no effect upon the appetite. Insulin, owing to its hypoglycemic action, stimulates appetite (p. 585); it also increases gastric tone.

Anorexia nervosa. A mental state leading to complete loss of appetite, or what really amounts to a morbid distaste for food of all sorts, was first described by Sir William Gull some 65 years ago and named *anorexia nervosa*. The subjects are usually nervous "high-strung" women. Some emotional upset may precipi-

tate the condition. Extreme emaciation, low metabolic rate, moderate hypoglycemia and amenorrhea are among the chief features. The appearance of the patient may suggest pituitary cachexia (Simmonds' disease, p. 738). Profound exhaustion results and death may occur from starvation. The aversion to food appears to be purely psychic, there being no evidence that some endocrine function is primarily at fault; nor is there any indication of organic gastric disease.

Thirst. The sensation of thirst is referred to the pharynx and is due to the stimulation of sensory nerve endings in this situation. Two theories have been advanced to explain the mechanism by which the sensation is aroused.

According to one view, thirst is due simply to the drying of the pharyngeal mucous membrane, the salivary glands being given a rôle in the regulation of the water balance of the body. When the water content of the body falls below a certain level salivary secretion is depressed, the consequent drying of the mucous membrane of the throat then elicits the characteristic sensation. If such a view is correct, drying of the pharyngeal mucosa from whatever cause should cause thirst. Cannon, who is the chief supporter of this theory, found in studies upon himself that after abstinence from fluids for a time the depression of salivary secretion which resulted was definitely associated with thirst. Atropine, which inhibits salivary secretion, also produced the typical sensation, and thirst aroused by the deprivation of water was relieved by the application of cocaine to the mucosa. Pilocarpine is also said to relieve thirst. In dogs, however, atropine and pilocarpine are without effect upon the water intake.

According to the other view, the thirst sensation is due to changes in blood composition, probably to a rise in its osmotic pressure, which stimulates the afferent nerve endings; or acts perhaps upon central nervous structures. Rowntree and his associates, for example, found that the thirst of diabetes insipidus was relieved neither by cocaineization of the mucous membrane nor when salivation was induced by pilocarpine. The experiments of Gilman suggest that cellular de-

hydration rather than a rise in osmotic pressure is the prime factor in arousing thirst. Elevation of the osmotic pressure of the blood in dogs, induced by the intravenous injection of hypertonic solutions of NaCl, caused a much greater intake of water than an equivalent rise in osmotic pressure caused by the injection of urea. After NaCl administration the ingested water quickly reduced the osmotic pressure of the blood to the pre-injection level, whereas after the injection of urea the osmotic pressure remained elevated. In support of the view that a lowered water content of the cells is the true thirst stimulus, Gilman cites an experiment in which anhydremia was induced by the withdrawal of large quantities of extracellular electrolytes (e.g., NaCl) without the withdrawal of water. In such anhydremic animals hydration of the tissue cells occurs, and though the oral mucous membranes are quite dry there is no evidence of thirst—water is refused.

It is not possible to make a definite choice between the two theories; evidence can be cited in support of either. It is probable that the factors concerned in the production of the sensation are both local and general. Experiments upon dogs in which the salivary glands were extirpated might be expected to provide a decisive answer. Such procedures however, have yielded conflicting results. Though some observers have reported an increased water consumption after the operation, others have been unable to obtain any evidence that removal of the glands induced thirst.³ A positive result, nevertheless, carries more weight than a negative one since mucus-secreting glands are scattered diffusely over the mucosae of the buccal and pharyngeal cavities.

The sensations and severe nervous symptoms which result from prolonged water deprivation are, of course, general in character and cannot be attributed to simple drying of the pharyngeal mucosa. They are dependent, no doubt, upon changes in blood composition and the dehydrated state of the tissues (p. 17).

SECTION VI. METABOLISM AND NUTRITION

CHAPTER XLVI

GENERAL METABOLISM

Metabolism is the term employed to embrace the various chemical processes occurring within the tissues upon which the growth and heat production of the body depend and from which the energy for muscular activity and for the maintenance of vital functions is derived. *Catabolism* is the term employed to embrace chemical reactions involving the breakdown or decomposition of substances into their simpler constituents. *Anabolism* is the word used to connote building up or assimilative processes.

HISTORICAL SURVEY AND GENERAL PRINCIPLES

The modern science of metabolism may be taken to date from the experiments of Lavoisier, carried out toward the end of the eighteenth century. He demonstrated that animal heat was the result of the oxidation of carbon in the body, and compared the process to the burning of a candle or any other combustible material. The process in either case involved the consumption of oxygen and the formation of carbon dioxide. Lavoisier and the physicist Laplace placed a guinea-pig in a closed chamber and determined the quantity of carbon dioxide eliminated in a 10-hour period. The same quantity of carbon dioxide was found to be produced by the animal's body as when 3.3 grams of pure carbon were burned in air. The guinea-pig was next placed in a closed space surrounded by ice. The heat given out by the animal's body during a 10-hour period was calculated from the quantity of ice which had melted (fig. 216). Three and three-tenths grams of carbon burned in a similar ice calorimeter were found to generate an amount of heat comparable with that given off by the animal. It was therefore concluded that the heat generated by the animal and the carbon dioxide eliminated by the lungs were the result of the combustion of approximately 3.3 grams of the body's carbon. *Thus, the parallelism between the amount of heat generated in the animal body and the quantity of carbon dioxide eliminated was demonstrated.*¹ A few years earlier Crawford, using a water calorimeter, had demonstrated a parallelism between the oxygen used and the heat generated. He found that a guinea-pig gave out a definite quantity of heat for every 100 ounces of oxygen

¹ Lavoisier, however, believed that the heat was produced through the oxidation of carbon and hydrogen in the lungs. Not until some years later was it shown that the site of the heat production was the result of the combustion of foodstuffs in the various tissues of the body.

which it consumed. When this quantity of oxygen was used in the burning of carbon outside the body, approximately the same quantity of heat was produced.

A summary of the work of later investigators and of the fundamental principles upon which modern studies in metabolism are based will now be given.

(1) Heat values of the foodstuffs

About half a century after the experiments of Lavoisier the work of Joule (1842) demonstrated the mechanical equivalent of heat, and Mayer and Helmholtz (1845) discovered the law of the conservation of energy which states that the sum total of energy in the universe remains constant, but that one form of energy, potential, mechanical, electrical, etc., may be converted into another. Through the work of Voit, Pettenkofer and Rubner this law was shown to hold true for the animal body. Rubner determined the heat produced by the three types of food when burned outside the body in a calorimeter and thus established their heat values. He then measured directly the heat given off by a dog placed in a calorimeter and found that for fat and carbohydrate the heat production was the same within experimental error whether combustion occurred within or outside the body. For protein the heat production was less when metabolized (*physiological heat value*) than when burned in a calorimeter. The reason for this is that unlike carbohydrate and fat, which are completely oxidized in the body to CO_2 and water, the combustion of protein by the tissues is incomplete. The carbon part of the molecule is burned but the nitrogen is excreted in the urine as urea and other nitrogenous compounds which possess a certain energy value. Burned outside the body, protein yields 5.3 Calories as compared with its physiological heat value of 4.1. The following are the quantities of heat generated by the metabolism of 1 gram of the respective foodstuffs:

1 gram of fat	yields 9.3 Calories
1 gram of carbohydrate	yields 4.1 Calories
1 gram of protein	yields 4.1 Calories

The caloric values of different types of carbohydrate and protein are not identical. The value for starch, for example, is 4.20 and for sugar 3.96. The value is higher for animal than for vegetable protein. There is also a small energy loss during digestion. For these reasons the respective values for fat, carbohydrate and protein in a mixed human diet are usually taken at 9.0, 4.0 and 4.0 respectively.

most cases over several days, when added to the heat equivalent of the excreta (urine and feces) was found to correspond, within about 1 per cent, to the calculated heat value of the ingested food. In other words, the energy intake and output balanced and the application to the body of the law of the conservation of energy was demonstrated. (See table 38.)

Corresponding results were obtained by Atwater for man. Rubner also demonstrated that the heat production of an animal as measured directly (direct calorimetry) agree within 1 per cent of that calculated indirectly from the respiratory exchanges (indirect calorimetry)—a brilliant confirmation of the conclusion arrived at by Lavoisier 100 years earlier.

(3) The respiratory quotient

Since the relative amounts of oxygen and carbon contained in the molecules of the three food-stuffs differ, the relative volumes of oxygen consumed and of carbon dioxide produced during the metabolism of each type of food also varies. The ratio $\frac{\text{vol. CO}_2 \text{ expired}}{\text{vol. O}_2 \text{ inspired}}$ is called the respiratory quotient or, briefly, the R. Q.

The following equation represents the oxidation of glucose:

It is clear from this equation that no oxygen is required from a source outside the food itself for the oxidation of the hydrogen in the glucose molecule, and that for each molecule of O_2 absorbed a molecule of CO_2 is produced. It will also be recalled that according to the law of Avogadro quantities of any two gases containing the same number of molecules and under identical conditions of temperature and pressure have equal volumes. In the metabolism of 100 grams of glucose, 75 liters of oxygen are required from the outside for its complete combustion, i.e., for the oxidation of the carbon; 75 liters of carbon dioxide are therefore produced. The respiratory quo-

tient, then is, $\frac{75}{75} = 1.0$. For the combustion of 100 grams of fat, (e.g. triolein $C_3H_5(C_{18}H_{33}O_2)_3$), which is rich in carbon and hydrogen but relatively poor in oxygen, 200 liters of the latter gas are required; 142 liters of carbon dioxide and about 110 grams of water are produced. The R.Q. is therefore $\frac{142}{200} = 0.71$. The R.Q. of protein is

FIG. 216. Ice calorimeter of Lavoisier and Laplace. (After Luciani.)

* From Lusk after Rubner.

(2) The energy balance

Rubner placed a full-grown dog in a calorimeter (p. 526) in which the heat production could be measured directly. He fed the animal measured amounts of food for which the actual heat values had been calculated. The heat generated by the animal during the experiment, which extended in

0.80 and of alcohol 0.67. The value of the respiratory quotient is taken as an indication of the *type* of food being metabolized. It gives no quantitative estimation of the metabolism. An R.Q. around unity is taken to indicate that the material being used is chiefly carbohydrate; one around 0.70 indicates that it is mainly fat.²

On an ordinary mixed diet the respiratory quotient is about 0.85 and in the postabsorptive state (p. 533) about 0.82. In the formation of fat from carbohydrate, as in the fattening of farm animals, an oxygen-rich substance is being converted into one poor in oxygen. Oxygen is liberated in the conversion and less, in consequence, is taken in from the outside for general oxidative processes. The respiratory quotient may therefore rise above unity (up to 1.4). A very low quotient, as is seen in the hibernating animals, is supposed by some to indicate the reverse process, i.e., the conversion of fat to carbohydrate. In the hibernating marmot the R.Q. is between 0.6 and 0.7.

(4) Thermal Equivalents

As mentioned on page 522 the heat production bears a relation to the oxygen consumed and the carbon dioxide eliminated. Consequently, if one knows the quantity of either of these respiratory gases consumed or exhaled, respectively, during a given period, the heat production of the body during that time can be calculated. The heat production for a given quantity of these gases varies, however, with the type of food undergoing combustion. For instance, when carbohydrate is burned the consumption of a liter of oxygen causes a greater evolution of heat (5.047 Cal.) than when fat is burned (4.686 Cal.). This is so because a larger part of the oxygen required for the complete combustion of the former substance is, as mentioned above, contained within its own molecule. The value for protein is 4.485 Calories. The heat equivalent of CO₂ varies much more than does that of oxygen; for example, a liter of CO₂ formed in the combustion of carbohydrate represents the evolution of 5.047 Calories, whereas, the heat equivalent of this volume of CO₂, when the fuel is fat, is 6.629 Calories.

It is therefore more usual to calculate the heat production from the oxygen consumption; but

² Cathcart and Markowitz point out, however, that probably too much reliance has been placed upon the value of the respiratory quotient as an unequivocal criterion of the type of foodstuff undergoing metabolism. The R.Q. in a given instance is undoubtedly a resultant of several different metabolic processes—syntheses and interconversions as well as combustion.

even so, the food mixture undergoing combustion, as indicated by the respiratory quotient, must be taken into account. The heat or caloric values (thermal quotients) of a liter of oxygen at different respiratory quotients is given in table 39 compiled by Zuntz and Schumburg (as modified by Lusk).

In table 39 the percentage of fat and carbohydrate undergoing combustion have been calcu-

TABLE 39
(After Zuntz and Schumburg, modified by Lusk*)

NON-PROTEIN RESPIRATORY QUOTIENT	CALORIES PER LITER O ₂	CALORIES DERIVED FROM	
		Carbohydrate	Fat

1.00	5.047	100.0	0

* This table has been further modified by Cathcart and Cuthbertson, see J. Physiol., 1931, 72, 349.

lated for respiratory quotients ranging from 0.707 to 1.0. These so-called *non-protein respiratory quotients* were obtained by determining the total oxygen consumption and carbon dioxide produced and then subtracting the volumes of these gases exchanged in the catabolism of protein. The quantity of protein undergoing catabolism is obtained from the urinary nitrogen, each gram

of the latter being equivalent to 6.25 grams of protein. In precise experiments upon heat production, the calories produced from the catabolism of protein as well as those derived from fat and carbohydrate would require to be determined. For example, a subject produces per hour 13.50 liters of carbon dioxide, consumes 16.00 liters of oxygen and excretes 0.5 gram of nitrogen in the urine. Now, each gram of urinary nitrogen represents the production of 4.76 liters of carbon dioxide and the consumption of 5.94 liters of oxygen.

Therefore:

the CO₂ produced by the subject in the catabolism of protein is $0.5 \times 4.76 = 2.38$ liters
the O₂ consumed in the catabolism of protein is $0.5 \times 5.94 = 2.97$ liters

Then:

the non-protein CO₂ production is $13.50 - 2.38 = 11.12$ liters
the non-protein O₂ consumption is $16.00 - 2.97 = 13.03$ liters
the non-protein respiratory quotient is $\frac{11.12}{13.03} = 0.85$.

It will be seen from table 39 that at this R.Q. the caloric equivalent of a liter of oxygen is 4.862. The heat produced by the combustion of non-protein materials is therefore, $13.03 \times 4.862 = 63.3$ Calories of which 50.7 per cent is derived from carbohydrate and 49.3 per cent from fat.

The heat production due to protein is $2.97 \times 4.485 = 13.3$ Calories. (The caloric equivalent of each gram of urinary N is 26.51, so, the heat production due to protein may also be obtained approximately by multiplying the figure for the urinary nitrogen (0.5) by 26.51.)

The total heat production per hour is therefore $63.3 + 13.3 = 76.6$ Calories. Of this, 42 per cent is derived from carbohydrate, 41 per cent from fat and 17 per cent from protein.

In ordinary determinations of the basal metabolic rate (p. 533) urinary nitrogen is not measured and the foregoing calculations are not undertaken; only a slight error is involved if the R.Q. is assumed to be 0.82 and the heat production taken directly from table 39.

(5) The isodynamic law

It was demonstrated by Rubner that just as the production of heat by a stove may be main-

tained at a constant level by burning different types of fuel, so in the generation of animal heat the different foodstuffs may replace one another in the diet in accordance with their heat producing values. Thus:—

- 100 grams of fat
- 232 grams of starch
- 234 grams of cane sugar
- 243 grams of dried meat

produce equivalent amounts of heat when ingested, i.e., they are isodynamic.

(6) Heat production in relation to surface area

TABLE 40

Showing relation of heat production per kilogram and per square meter of body surface in animals of different sizes

	WEIGHT	CALORIES	
		Per kilogram	Per square meter surface
	kgm.		
Pig.....	128.0	19.1	1,078
Man.....	64.3	32.1	1,042
Dog.....	15.2	51.5	1,039
Goose.....	3.5	66.7	967
Fowl.....	2.0	71.0	947
Mouse.....	0.018	654.0	1,188

The relatively low figures for the heat production of birds shown in the last column is due to their bodies containing a high proportion of osseous tissue which has an extremely low metabolism.

The heat produced by an individual at rest is proportional to the surface area of his body. Thus a fasting adult man and a starving dog, though the surface area of each and the total heat production were widely different, were shown by Rubner to give out in 24 hours closely similar amounts of heat per square meter of body surface, namely, 1134 and 1112 Calories respectively. A small animal, e.g., a mouse, therefore, since its surface area is greater in proportion to its mass, and since it generates the same amount of heat per unit of body surface, must obviously generate more heat per unit of body weight than a larger animal. The heat is produced in the tissues (muscles, liver, etc.); consequently these, in the case of the smaller animal, must be the seat of a much more active metabolism (see table 40).

(7) Physiological conditions which stimulate metabolism

The heat production of the body is increased by (a) muscular work, (b) food, (c) a fall in

environmental temperature, or (d) a rise in body temperature (fever). These influences will be considered later.

CALORIMETRIC METHODS

THE BOMB CALORIMETER

The bomb calorimeter is employed for the determination of the potential energy of food. The food is dried and a weighed quantity ignited, by means of an electric fuse, in a hollow steel container lined with platinum and filled with pure oxygen (fig. 217). The heat evolved (energy of the food converted to heat) is absorbed by a

FIG. 217. Bomb calorimeter. A, platinum dish holding food sample; B, bomb filled with pure oxygen; C, vessel containing water, in which bomb is submerged; D, outer double-walled insulating jacket; E, fuse, which is ignited by an electric current; F, motor-driven water stirrer; G, thermometer; H, electric wires to send current through fuse. (After Rose.)

known quantity of water in which the container is immersed. The quantity of water in kilograms (plus the water equivalent of the apparatus) multiplied by the number of degrees centigrade through which its temperature has been raised gives, in Calories, the quantity of heat generated.²

² Another type of calorimeter called the *oxy-calorimeter* has been devised by Benedict. The caloric value of the food is determined by burning a sample in a special combustion chamber and measuring the *volume of oxygen* used. Knowing the caloric equivalent of a liter of oxygen used in the combustion of the three foods stuffs (p. 524) the heat value of the particular food sample is readily calculated. This method is really an adaptation of the method of indirect calorimetry used in the clinic and described on page 528.

CALORIMETRIC MEASUREMENTS IN ANIMALS AND MAN

An animal's energy is derived from the food which is to the body what fuel is to a furnace or machine. We have seen that the law of conservation of energy holds true for the animal body—that in a healthy animal which is maintaining a constant weight the intake and output of energy are equal. The food undergoes combustion in the tissues, its carbon being oxidized to carbon dioxide, its hydrogen to water and its potential energy converted into other forms of energy—mechanical, electrical, chemical and thermal. Thus the various processes of life are sustained. In a growing animal or in an animal during fattening the energy of the food is in part stored as new-formed tissue.

In the resting body all the energy liberated from the food ultimately appears as heat. A heat unit has therefore been chosen as the most convenient one for measuring and expressing the energy exchanges of the body. This unit is the *large calorie* (Calorie or Cal.), i.e., the quantity of heat required to raise the temperature of a kilogram of water 1 degree centigrade (actually from 15° to 16°C.). The Calorie used in physiological determinations is therefore 1000 times the *small calorie* (calorie or cal.) used in physical measurements.

Calorimetric methods are of two main types: (a) *direct* which is the same in principle as that described above for the bomb calorimeter, and (b) *indirect* in which the heat production is calculated from the respiratory exchanges.

Direct calorimetry

The elaborate nature of the apparatus required for this method precludes its use, especially for the human subject, in any ordinary laboratory or clinic. There are indeed only a very few in existence.

The apparatus consists of an insulated chamber large enough to accommodate an animal or a man. The heat eliminated from the body is absorbed by water circulating in coils of copper pipes. The temperature within the chamber is kept constant and the temperature of the subject is taken from time to time to ensure that heat is not being retained. The heat generated and radiated by the subject is absorbed by the circulating water. The temperature of this as it enters and leaves the chamber being known, and also its quantity (kilograms), the heat production in Calories can be determined. To this must be added the latent heat of the water vapor given off by the lungs and skin.

This, which amounts to about one-quarter of the total heat production, is calculated from the weight of the water in grams removed from the air by an absorber (sulphuric acid) multiplied by the factor 0.59 Calorie which is the latent heat of 1 gram of vaporized water at 20°C. A calorimeter of this type is usually combined with apparatus for determining the heat production by

FIG. 218. Schematic diagram of the Atwater-Rosa-Benedict respiration calorimeter. Ventilating system: O_2 , oxygen introduced as consumed by subject; 3, H_2SO_4 to catch moisture given off by soda lime; 2, soda lime to remove CO_2 ; 1, H_2SO_4 , to remove moisture given off by patient; B1, blower to keep air in circulation. Indirect calorimetry: Increase in weight of H_2SO_4 (1) = water elimination of subject; increase in weight of soda lime (2) + increase in weight of H_2SO_4 (3) = CO_2 elimination; decrease in weight of oxygen tank = oxygen consumption of subject. Heat-absorbing system: A_1 , thermometer to record temperature of ingoing water; B, thermometer to record temperature of outgoing water; V, vacuum jacket; C, tank for weighing water which has passed through calorimeter each hour; W, thermometer for measuring temperature of wall; A_1 , thermometer for measuring temperature of the air; R, rectal thermometer for measuring temperature of subject. Direct calorimetry: Average difference of A and B \times liters of water + (gm. water eliminated \times 0.586) \pm (change in temperature of wall \times hydrothermal equivalent of box) \pm (change of temperature of body \times hydrothermal equivalent of body) = total calories produced. Th, thermocouple; Cu, inner copper wall; Cu_2 , outer copper wall; E, F, dead air-spaces. (After Lusk, *The Science of Nutrition*.)

indirect calorimetry as described below, the instrument being then referred to as a respiration calorimeter (fig. 218).

Indirect calorimetry: determination of the heat production from the respiratory exchanges

Experiments by several observers upon man and animals have shown that the results of

indirect calorimetry agree within less than 1 per cent with those obtained by the direct method. Two forms of apparatus—*closed-circuit* and the *open-circuit* or *air-current* types—are employed for indirect calorimetry. In the first mentioned method the subject rebreathes the air contained in a closed system; the carbon dioxide eliminated by the subject is removed by soda-lime and weighed; a measured volume of oxygen is supplied to replenish that which has been absorbed. In the open-circuit type, the subject inspires room air and expires into some form of container: the entire volume of expired air is measured and a sample analyzed for its carbon dioxide and oxygen percentages. Among the closed-circuit types of apparatus are those of Regnault and Reiset, and of Benedict and associates. The Douglas bag and Tissot methods are of the open-circuit type. In Haldane's method for small animals, though it is of the open-circuit or air-current type, the carbon dioxide is absorbed and weighed.

THE CLOSED-CIRCUIT METHODS:

In the Regnault-Reiset type of apparatus, the air is circulated through a closed system of which a chamber, large enough to accommodate the subject, forms a part. The air in the system is rebreathed repeatedly, carbon dioxide and water vapor being removed and oxygen supplied to replace that consumed. The air upon leaving the chamber enters first an absorbing vessel containing sulphuric acid which removes the moisture, then through a container filled with moist soda-lime which removes the carbon dioxide, and finally through a second sulphuric acid container which abstracts the water gained from the soda-lime. The dried and carbon dioxide-free air is then returned to the chamber. The quantity of carbon dioxide eliminated by the animal is given by the difference between the weights of the soda-lime container at the beginning and end of the experiment. Oxygen is run into the system from a cylinder and measured by means of a gas meter or by weighing the cylinder at the beginning and end of the experiment. The air in the chamber is analyzed at the end of the observation in order to ensure that no change in its composition has occurred. Only a few institutions on this continent, such as the Russell Sage Institute in New York and the Nutrition Laboratory at Washington, possess an apparatus of this type suitable for metabolic studies upon man. Such an apparatus was first constructed in America by Atwater and Rosa. It is usually combined with an apparatus of the direct type (fig. 218). The construction of a closed circuit type of apparatus for laboratory animals is not, however, such a difficult matter (fig. 219).

In other closed-circuit methods, such as the one described below, the subject is not enclosed

within a chamber; he simply breathes in and out of the apparatus through a connecting tube.

the closed system and both carbon dioxide elimination and oxygen usage were determined. In the

FIG. 219. Schematic outline of respiration apparatus for small animals. The air leaves the chamber at A and, after passing through the rotary blower B, which keeps the ventilating current in motion, is forced through the glass vessel C, which serves as a safety trap. The air then passes through the bottles C, D and E containing sulphuric acid to remove the moisture. The air, now water-free, but containing the CO_2 produced by the animal and lacking the O_2 which the animal has consumed, passes into the 2-way valve V_1 , where it may be deflected into the bottle F containing soda lime for the absorption of CO_2 . The moisture gained from the soda lime is absorbed by sulphuric acid in bottle G. The air then passes through a second 2-way tap V_2 to H containing dry sodium bicarbonate which removes the traces of acid vapor taken up by the air in passing through bottle G. J is a glass vessel containing water which supplies sufficient moisture to the air for the comfort of the animal. K is a by-pass valve. The chamber is constructed of copper and has a cover with a water seal M. N is a glass plate through which the animal can be observed. O is a spirometer attached to the system on the intake side of the rotary blower B. (From F. G. Benedict.)

FIG. 220. Benedict-Roth apparatus (courtesy of Warren E. Collins, Inc., Boston).

Clinical types of closed circuit apparatus In the earlier clinical types the subject was connected by means of a mouthpiece and flexible tubing to

type most commonly used today—the Benedict-Roth apparatus (figs. 220 and 221)—the heat production is calculated from the oxygen consumption alone. In order to purify the air the carbon dioxide is absorbed by soda-lime but the amount of this gas eliminated is not measured. In determining the basal metabolism (p. 533) the subject lies upon a couch and breathes in and out of the instrument through a mouthpiece and two wide-bore tubes (inspiratory and expiratory) provided with valves. The nose is clipped. The main part of the instrument consists of a bell-type spirometer. This is a hollow double-walled cylindrical vessel. In the narrow space between the two walls fits a second inverted hollow cylindrical vessel or bell. The bell is counterpoised so that it rides easily up or down in the annular space between the two walls. This space contains water which acts as a seal. At the commencement of the experiment, sufficient oxygen is admitted from an oxygen cylinder to raise a pointer on the spirometer bell to the zero mark upon an adjoined scale which has been calibrated to oxygen volumes. The breathing of the subject

through the inspiratory and expiratory tubes keeps the air circulating freely through the

FIG. 221. Sectional view of Benedict-Roth closed circuit respiration apparatus.

FIG. 222. Haldane's respiration apparatus. 1 and 4, soda lime; 2, 3 and 5, pumice stone soaked in sulphuric acid; Ch, animal chamber; M, meter. J is an inverted bell-jar standing in a trough of water, it serves to prevent sudden excess of negative pressure and to indicate the pressure actually employed. P, pump. (After Haldane.)

system. As oxygen is consumed the spirometer falls and from the difference in the levels of the pointer at the beginning and end of the experiment the oxygen usage is calculated. The volume of oxygen used, dry and reduced to standard temperature and pressure (see p. 531) is then

calculated. The heat production is found by reference to the table of respiratory quotients given on page 524. The average R.Q. in the postabsorptive state (see p. 533) is 0.82. Since the R.Q. of the subject is not determined by the foregoing method this value (0.82) is assumed. It will be seen from table 39 that at this R.Q. the caloric equivalent of 1 liter of oxygen is 4.825.

OPEN-CIRCUIT OR AIR-CURRENT METHODS:

In the *Haldane* type of calorimeter (which is suitable only for small animals, mice, rats or rabbits) a current of air is drawn through the system (fig. 222). Carbon dioxide and water are removed from the air before it enters the chamber and again after its exit therefrom. The carbon dioxide absorber on the outgoing current of air is weighed at the commencement and end of the experiment as in the Regnault-Reiset method, in order to obtain the quantity of carbon dioxide eliminated. The system with the exception of the first pair of absorbers and including the animal is then weighed. Since only oxygen has entered this part of the system (the air being CO_2 -free and dry) the gain in weight during the experiment gives the quantity of oxygen consumed by the animal.

The Douglas bag and Tissot methods (gasometric methods). In these methods the subject inspires atmospheric air and expires into a bag (Douglas method) or into a large bell-type spirometer (Tissot method). At the end of the experiment the total volume of expired air is measured and samples are analyzed for carbon dioxide and oxygen.

(a) *The Douglas-bag method.* The apparatus consists of a rubber-lined bag of from 60 to 100 liters capacity, a wide (20 mm.) flexible tube fitted with a flanged mouthpiece and a pair of rubber flutter valves similar to those used in gas masks. The valves are so arranged that the subject's inspired air is drawn from

the room while his expired air is directed into the bag (fig. 223, A). A three-way tap is situated at the junction of the bag with the tubing. In one position of the tap the subject can *expire* through the tubing into the outside air; breathing in this way for a short preliminary period enables him to become accustomed to the apparatus. At the commencement of the actual experiment the tap is turned so that the expired air enters the bag. At the end of the experiment the bag is closed by turning the tap back to the first position. The mouthpiece is then removed and the end of the flexible tubing connected with a gas-meter. A gas sampling tube is attached between the bag and the meter (fig. 223, B). The three-way tap is now opened and the bag compressed and finally rolled up in order to drive its

gas analysis apparatus, saturated with water vapor and its volume measured (fig. 225). It is then passed back and forth through the bulb containing potassium hydroxide solution which absorbs the carbon dioxide. It is then measured again. The difference between the two measurements gives the volume of carbon dioxide in the sample. Next, the oxygen is removed by passing the sample through a solution of potassium pyrogallate. The sample is measured a third time and the shrinkage in volume as shown by the difference between the second and third readings gives the quantity of oxygen absorbed. From the data

FIG. 223. Showing A, Douglas bag and tubing; B, Douglas bag with sampling bulb attached and gas meter for measuring the total volume of expired air (after Douglas and Priestley); C, subject equipped with Douglas bag apparatus during running or other types of muscular exercise. (After Hill.)

contents through the meter. During this procedure a specimen of expired air is taken for analysis. The Douglas method has the advantage that it can be employed for determining the metabolism during various types of muscular exercise, e.g. walking, running, etc. (fig. 223, C).

(b) *Tissot's method* is similar in principle to the foregoing. The subject expires into a large bell-type spirometer (capacity of 100 liters or more). The rise in the spirometer bell during the experiment is indicated by a pointer and scale. From this reading the total volume of expired air is derived. Samples of the latter are analyzed (fig. 224).

Gas analysis. The sample of expired air is drawn into the graduated burette of a Haldane

FIG. 224. Diagram of Tissot spirometer.

so obtained the percentages of carbon dioxide and oxygen in the sample of air are calculated.

Calculation of results. The following illustrates the steps in an actual metabolism experiment, using the Douglas or Tissot method.

Period of observation 10 minutes, barometer 750 mm. Hg.

Volume of expired air as read from meter (Douglas method) or as indicated by spirometer (Tissot method) = 70 liters.

Temperature of expired air (in meter or spirometer) = 20°C.

The volume of the gases must be reduced to standard conditions, namely, to 760 mm. Hg pressure and 273° absolute temperature (i.e., to 0°C.), and dry (i.e.,

the pressure of water vapor must be deducted from the barometer reading). The pressure of water vapor at 20°C. is 17.5 mm. So the corrected reading is;—

$$751.5 - 17.5 = 734.0 \text{ mm.}$$

FIG. 225. Haldane gas analysis apparatus (small pattern) showing a gas sampler in position. A, glass tube connected to gas sampler; B, gas burette; C, control tube; D, caustic soda absorption pipette; E, caustic soda reservoir; F, caustic pressure tube; G, pyrogallol absorption pipette; H, caustic soda seal; J, water jacket; M, aeration tube; R, mercury reservoir; X, one-way tap to control movements of mercury; Y, screw clip for fine adjustments of pressure in K after the tap has been closed; R.S., mercury reservoir for gas sampler; S.T.1 and S.T.2, taps of gas sampler with double ports; r and t, side tubes by means of which when S.T.1 or S.T.2 are placed in position, the "dead spaces" of these taps and of the tube A can be filled with mercury; a, rubber connection, any air bubble in A may be expelled here as described in text; F, pressure tube for control; K, pressure tube for burette. Note T3 usually a three-way tap, placed at the junction of the vertical and horizontal tubes. (From Lamb, *An Introduction to Human Experimental Physiology*.)

the volume of the expired air at standard pressure and temperature (S. P. T.) and dry is therefore

$$70 \times \frac{734}{760} \times \frac{273}{273 + 20}$$

$\times 0.8993 = 62.95$ liters during the period of observation (10 minutes) or 6,295 cc. per minute

In practice these detailed calculations are avoided by reference to table 41 which gives the required factor by

which the observed volume is multiplied in order to reduce it to standard conditions and dry.

Results of gas analyses:

Expired air	Inspired air
CO ₂ = 3.50 per cent	CO ₂ = 0.04 per cent
O ₂ = 16.90 per cent	O ₂ = 20.93 per cent
N ₂ = 79.60 per cent	N ₂ = 79.03 per cent

Since the O₂ percentages in expired and inspired airs are 16.90 and 20.93 respectively it might be thought that 20.93 - 16.90 would give the percentage of O₂ absorbed. It will be noticed, however, that the percentage of N₂ is higher in the expired than in the inspired air. Nitrogen is inert insofar as respiration is concerned, being neither produced nor retained in the body, i.e., its absolute amount is not altered. Therefore, its greater proportion in the expired air can only mean that the volume of the inspired air (which of course was not measured) must have been greater than that of the dry expired air. So then, the volume of O₂ inspired must also have been greater than appeared from the analysis of the expired air. The cause of the discrepancy is that part of the absorbed oxygen has combined with hydrogen and in other ways, and so has not appeared as CO₂. The extent to which the O₂ in the inspired air exceeds that shown by the analysis of the expired air is proportional to the increased percentage of N₂ in the latter. Instead of the inspired air having contained 20.93 volumes of O₂ for every 100 volumes of air expired, it must have contained

$$20.93 \times \frac{79.60}{79.03}, \text{ or } 0.265 \text{ (a constant factor)} \times$$

$$79.60 = 21.09 \text{ volumes.}$$

Therefore the O₂ absorption is

$$\frac{21.09 - 16.90}{100} \times 6295 = 264 \text{ c.c. per minute.}$$

The calculation is abbreviated by the use of table 42.

The quantity of CO₂ produced may be calculated without correction since its percentage in the inspired air is negligible. Hence:

$$\frac{3.50 - 0.04}{100} \times 6295 = 218 \text{ c.c. per minute.}$$

The respiratory quotient is therefore

$$\frac{\text{Vol. CO}_2 \text{ expired } 218}{\text{Vol. O}_2 \text{ absorbed } 264} = .82$$

The caloric values of O₂ and CO₂ are given in, or can be calculated from table 39, p. 524. The heat production may be calculated from either of these values. For example, when the R. Q. is .82 the caloric value of 1000 cc. of O₂ is 4.825. Therefore, 264 cc. of O₂ represents a heat production of $4.825 \times \frac{264}{1000} = 1.27$ cal. per minute or 76.20 cal. per hour.

THE BASAL METABOLIC RATE (B.M.R.)

This is the term applied to the heat production of a subject who though awake is as nearly as possible at complete *muscular* and *mental rest*, and in the *postabsorptive* state (i.e., from 12 to 14 hours after a light meal when, it is assumed, the digestive processes are quiescent). The room temperature should be 20°C. For example, the prospective subject of a basal rate determination is directed to refrain from undue muscular exertion or fatiguing effort of any kind for 24 hours previously. A light meal with the minimum amount of protein is taken not later than 7 o'clock the night before the test which is undertaken at

TABLE 42

79.4	21.04	80.5	21.33
79.5	21.07		

about 9 o'clock in the morning. For a period of 30 minutes or so before and during the test the subject should be lying down comfortably in a room with subdued lighting.

The apparatus most commonly employed for the determination of the basal metabolic rate in the clinic is the instrument of Benedict and Roth (p. 528). Tissot's method or the bag method of Douglas is also sometimes used.

BASAL METABOLIC RATE STANDARDS

We have seen that the metabolism is proportional to the body's surface area rather than to its weight (p. 525). For example, of two men of about the same age, one large and the other small, though the former has the greater total heat production, the heat production per unit of body surface is of practically the same value in both subjects. Consequently, since the surface area

of the larger man is, in proportion to his mass, less than that of the smaller, his heat production per unit of body weight must be less. In figure 226, A, are shown two wooden blocks. The volume and weight of the larger is some three times greater than that of the smaller, but its surface area is only twice as great. If the metabolic rate were accurately related to weight rather than to surface area, then of two similarly shaped animals differing in size to the same extent as the two blocks the metabolism of the larger would be three times greater than that of the smaller; it is found, however, to be only about twice as great.

FIG. 226. Description in text.

Also two objects of the same volume and weight will have different surface areas if they differ in shape. In figure 226, B, the board and block are identical in volume and weight but the surface area of the former is more than double that of the latter. The nearer an object approaches in shape to a cube or a sphere the less is its surface area in proportion to its bulk. So, of two men of the same weight one tall and the other short and stout the former will have a higher metabolic rate. It is possible that this explains, in part at least, why a man of thin build often eats more than a stouter man of about the same weight. Since normal adults do not differ very greatly in size

and shape, it may be stated as a rough approximation that the heat production of the human body is a Calorie per kilogram per hour. But for the reasons just given it is much more accurate to express the basal metabolism in terms of body surface. Thus, the average basal rate of normal men between the ages of 20 and 50 years is from 38 to 40 Calories per square meter of body surface per hour. This value is constant for all normal men whether they are tall, short, thin or stout, large or small. Knowing a subject's height and weight his surface area can be determined at a glance from the chart (fig. 227), from the nomogram shown in figure 228, or from table 43; or it may be calculated from the height-weight formula.⁴ The average surface area for adults in Canada and the United States is about 1.6 square meters for women and 1.8 for men; the total basal

FIG. 227. Chart for determining surface area in man in square meters. (After Du Bois.) Example weight 60 kilograms, height 170 cm. = 1.70 sq. m.

heat production of the majority of normal adults ranges from 1400 to 1800 Calories per day.

The heat production per square meter of body surface is arrived at by dividing the value for the total heat production per hour of the subject, as determined by one of the methods already described (p. 529), by the figure for the surface area. For example, a man 175 cm. tall weighing 75 kg. has a surface area of 1.91 sq. meters. His total heat production is, say, 76.20 Calories per hour. His heat production per square meter per hour is therefore

$$\frac{76.20}{1.91} = 39.8 \text{ Calories}$$

⁴ The formula introduced by Meeh and modified by DuBois and DuBois is as follows:

$$A = W^{0.725} \times H^{0.725} \times 71.84 \text{ (a constant),}$$

where A = surface area in square centimeters, W = weight in kilogram, and H = height in centimeters.

Having obtained this figure it is customary to express the B.M.R. as normal or as a percentage above (+) or below (-) the normal. Thus, in the foregoing example the rate would be said to be normal. If it were 30 Calories per square meter per hour it would be expressed as -25 per cent and if 50 Calories as +25 per cent. The age and sex must also be considered since 39.8 Calories per square meter though normal for a full-grown man of 25 years or so would be above normal for

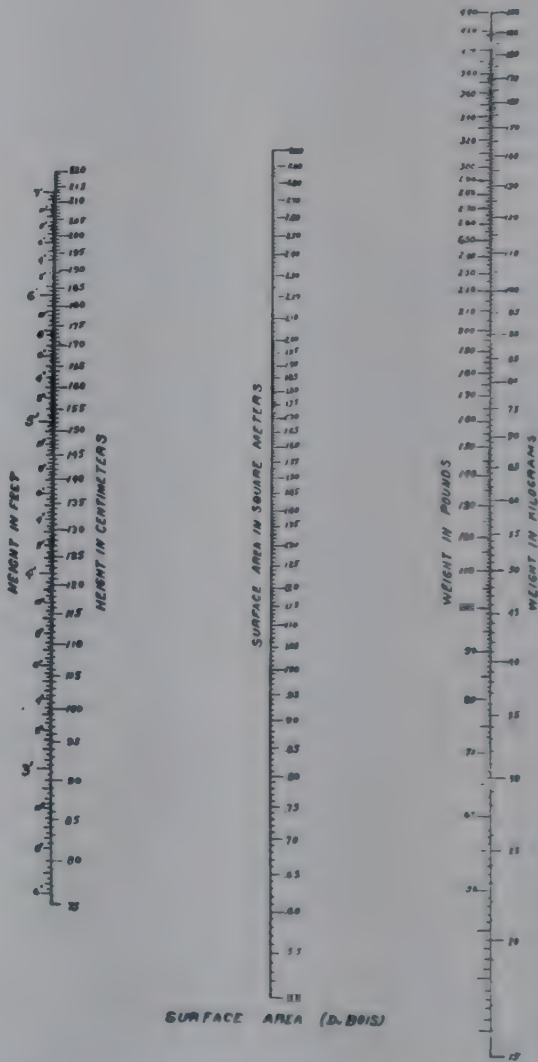

FIG. 228. Nomogram for surface area from weight and standing height, according to the formula of Du Bois. A line joining the weight and height of an individual crosses the scale of surface area at the required value. (After Boothby and Sandiford, from Du Bois, *Basal Metabolism*, Lea and Febiger. Philadelphia.)

a woman of the same age and below normal for a child (see below).

CONDITIONS WHICH INFLUENCE THE BASAL METABOLIC RATE

A. Physiological

(1) AGE AND SEX. The heat production per square meter of body surface diminishes progressively from infancy to old age being about 50 Cal. per square meter per hour at the age of ten or twelve and about 32 Cal. at 90 years

part completely oxidized, the nitrogen being excreted mainly as urea. The urine contains pyrimidines in insignificant quantities.

THE SYNTHESIS OF PURINES IN THE BODY

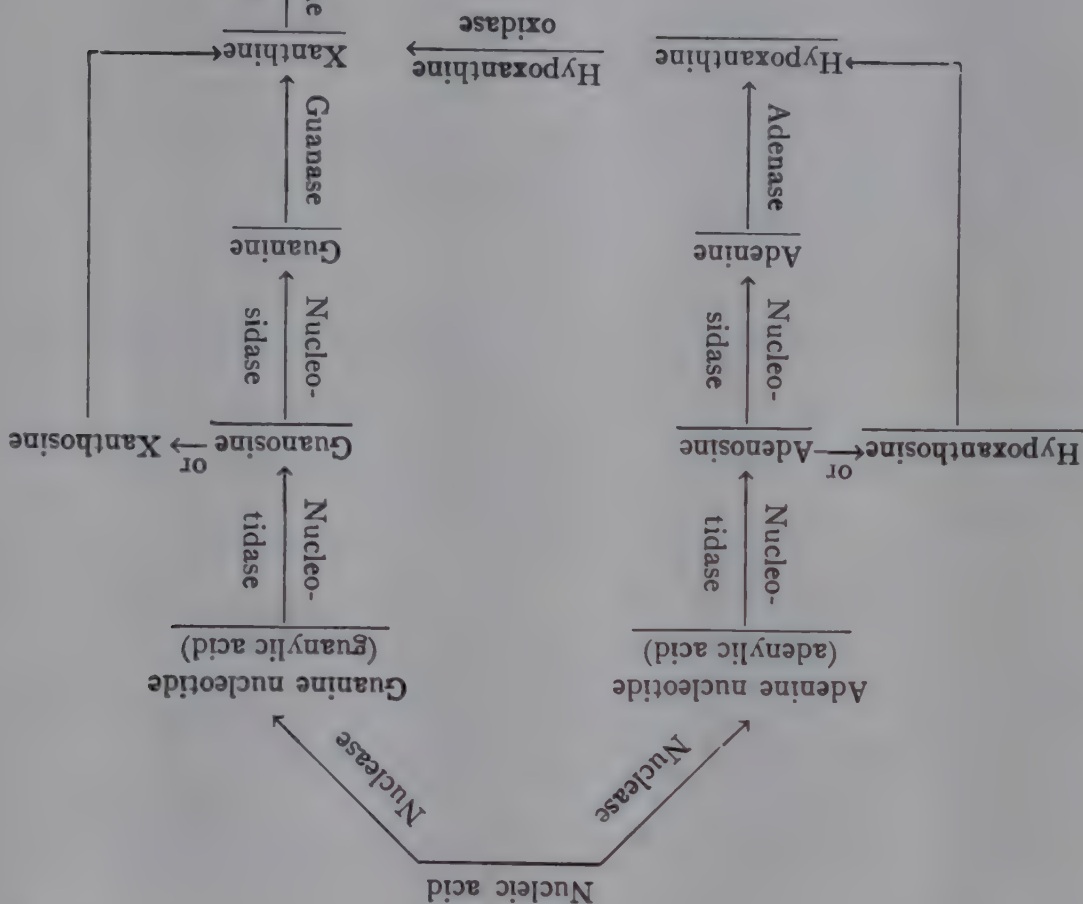

There is no doubt that purine synthesis occurs in the young mammal, for, when upon a diet comprised exclusively of milk, which is almost purine-free, it excretes uric acid or allantoin, and at the same time manufactures nucleic acid for the construction of cell nuclei. That synthesis also occurs in the adult was shown by Benedict, who kept a Dalmatian dog upon a purine-free diet for nearly a year, during which time the animal excreted 100 grams of uric acid. This had not apparently been derived from body tissue since the animal maintained a constant weight. The chief precursor of purines is histidine. A diet rich in this amino-acid increases the output of uric acid in the urine by over 30 per cent and is markedly decreased by a histidine-free diet.

THE PRODUCTION, DESTRUCTION AND EXCRETION OF URIC ACID

In man, uric acid is formed in part from purines taken in the food (*exogenous uric acid*) and in part from body purines (*endogenous uric acid*).

These animals would appear to possess an advantage over man, since allantoin is some 250 times more soluble than is uric acid. The conversion of uric acid to allantoin occurs in the liver (dog). Mann and his colleagues, for example, have shown that after hepatectomy uric acid accumulates in the blood, and when uric acid is injected, from 70 to 100 per cent can be recovered from the urine unchanged. This is in marked contrast to the behavior of the normal dog which excretes 98 to 100 per cent as allantoin. Extracts of dogs' liver are rich in uricase. The stages through which uric acid or allantoin is derived from nucleic acid are shown in the scheme below. The chemical changes involved in the conversion of guanine and adenine to uric acid or allantoin are indicated in the following formulae: (page 565).

Little is known concerning the fate of the pyrimidines in man. In animals they are for the most part excreted as allantoin. The spotted coach-dog (Dalmatian) oddly enough is an exception: like man and unlike other canine breeds it excretes uric acid.

(man, ape, birds and reptiles)

(mammals other than man and apes)

by a specific tissue enzyme, *adenase* to form *hypoxanthine*. Hypoxanthine is then oxidized by the enzyme, *hypoxanthine oxidase*, to *xanthine* which in turn is oxidized, by means of *xanthine oxidase*, to uric acid. The other purine, *guanine*, is converted by the deaminative action of *guanine* to *xanthine* and by further oxidation to uric acid. In mammals other than the primates 80 to 98 per cent (depending upon the species) or the uric acid is oxidized further by an enzyme, *wricase*,

upon hydrolysis nucleic acid is split into its constituent nucleotides. The purine nucleotides are termed *adenylic acid* and *guanylic acid*, respectively. The further action of hydrolytic agents splits off phosphoric acid from the nucleotides. The residue (sugar + purine or pyrimidine) is then called a *nucleoside*. The adenine-containing nucleoside is known as *adenosine*; the one containing guanine is called *guanosine*.

Three mononucleotides occur in tissues uncombined: the nucleic acid molecule, i.e., separate from other nucleotides. These are not derived from cell nuclei but are probably in combination with the cytoplasm. They are, (a) *adenyl-pyrophosphoric acid* (*adenosinetriphosphate*) present in muscle (p. 615); it differs from the adenine-containing mononucleotide in thymus nucleic acid in that its sugar, as in plant nucleic acid, is d-ribose; it differs from the mono-nucleotide of both animal and plant nucleic acids in containing pyrophosphoric acid. (b) *Hypoxanthine* (*inosinic acid*) also found in muscle is formed by deamination of adenine in (a) and the removal of two molecules of phosphoric acid; its purine is hypoxanthine and its sugar is d-ribose. (c) *Guanylic acid*, constituted of phosphoric acid, d-ribose and guanine is found in various glandular tissues (e.g., pancreas).

THE END PRODUCTS OF PURINE AND PYRIMIDINE METABOLISM

Nucleoprotein is split into protein and nuclein by the action of pepsin. The nuclein is hydrolyzed into protein and nucleic acid by trypsin. The nucleic acid is quite resistant to the action of either of these enzymes, but is split into its constituent nucleotides by means of enzymes—*nucleases*—contained in the intestinal juice and the intestinal wall. Through the action of tissue enzymes the nucleotides undergo a series of changes. First, they are hydrolyzed by *nucleotidases* in the intestinal wall into phosphoric acid and the corresponding nucleoside (adenosine or guanosine). Each of the latter is split in turn by the action of a *nucleosidase* into its pentose and purine (adenine or guanine) components. Nucleosidases are present in the intestinal wall as well as in the general tissues. The purines give rise to uric acid (see scheme, p. 566).

Uric Acid (first isolated by Steele in 1776 from urinary calculi). This urinary constituent is the end product of purine metabolism in man, higher apes, birds and reptiles. *Adenine* is deaminated in birds and reptiles uric acid is the end product of protein metabolism as well as of purine metabolism. According to Benedict from 60 to 70 per cent of the

urinary nitrogen of these species is in the form of uric acid. Of the intermediate stages in the production of uric acid from protein little is definitely known. According to Krebs and his associates, uric acid is synthesized in the bird's liver from ammonia, hypoxanthine being a primary product. The oxidation of hypoxanthine to xanthine is usually also attributed to xanthine oxidase; but according to Dakin, it is likely that a separate enzyme (hypoxanthine oxidase) is responsible for this change. The production of uric acid may follow another course, namely, conversion of the nucleoside adenosine or guanosine, by deamination, to hypoxanthine or xanthosine, which is then split into its pentose and purine groups, hypoxanthine or xanthine, respectively, (see plan on p. 566).

THE METABOLISM OF THE PURINE AND PYRIMIDINE BASES

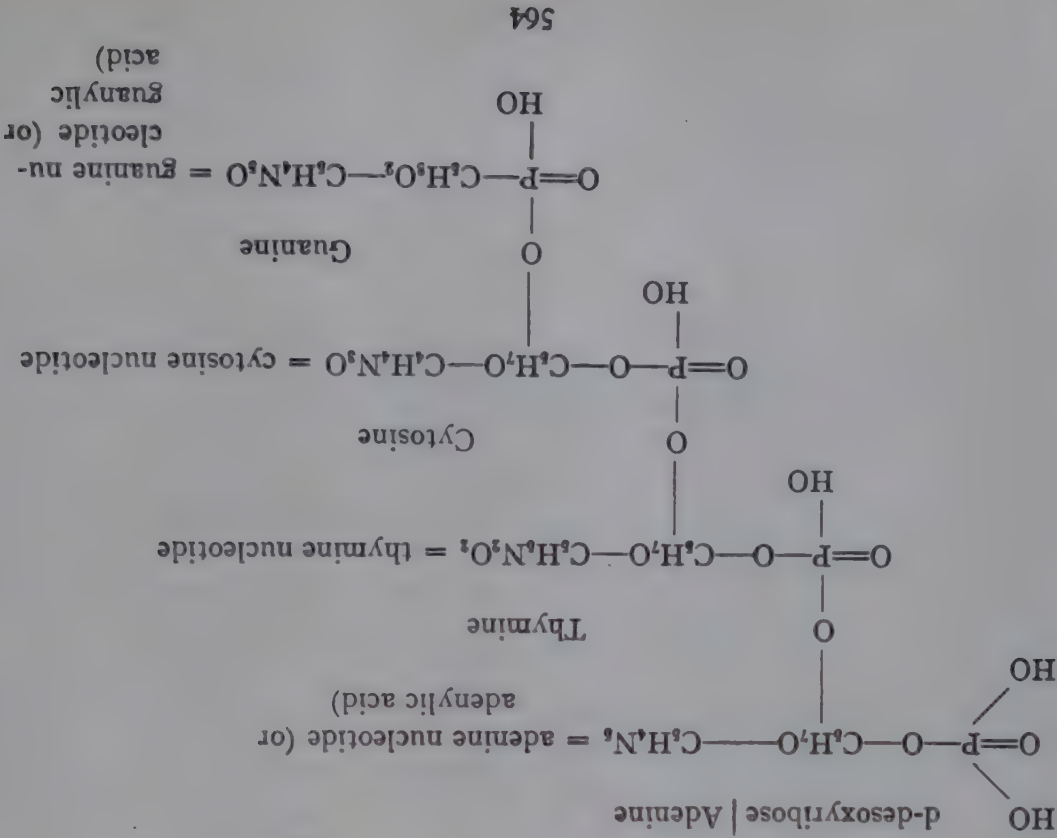

CHAPTER XLIX

One class of conjugated proteins—the *nucleo-proteins* (p. 539)—are compounds of simple basic proteins, *protamines* and *histones*, with *nucleic acid*. The protein is in salt-like combination with the acid but appears to be present in excess; when a nucleoprotein is hydrolyzed the excess is first split off leaving the substance called *nuclein*. This, upon further hydrolysis, yields protein and nucleic acid. Thus

Cell nuclei are composed largely of nucleoprotein; Miescher obtained this substance originally from pus cells and from the heads of the spermatozoa of salmon. There are two main varieties of nucleic acid. One is known as *thymus-nucleic acid*, the other as *yeast-nucleic acid*. They are also referred to as *animal nucleic acid* and *plant nucleic acid*, respectively. But thymus-nucleic acid is not, as it has been isolated from the nuclei of plant cells—rye embryos and yeast; plant nucleic acid was

Of the four mononucleotides in the nucleic acid molecule two contain each a purine base, and two each a pyrimidine base. The two purines are adenine ($C_5H_5N_9$) and guanine ($C_5H_5N_6O$). In thymus-nucleic acid the two pyrimidines are thymine ($C_5H_6N_2O_2$) and cytosine ($C_4H_5N_3O$). The sugar is *d-2-desoxyxyribose* ($C_5H_{10}O_4$), a 2-desoxyxypentose. Plant nucleic acid differs from the latter variety in that its sugar is *d-ribose* ($C_5H_{10}O_5$), and thymine is replaced by another pyrimidine—*uracil* ($C_4H_4N_2O_2$). Nucleic acids are therefore tetranucleotides. The following according to Levene is the structural formula of thymus nucleic acid.

instance, fed in any quantity, is inadequate for either growth or maintenance. Lactalbumin at a level of less than 8 or 9 per cent is incapable of promoting normal growth. Yet normal growth occurs on a diet containing 13.5 per cent zein and 4.5 per cent lactalbumin (fig. 230). The proportions of tryptophane and cystine and probably also of lysine are higher in lactalbumin than in body protein. Therefore, the excess of these amino-acids in lactalbumin, instead of being wasted, combines with the amino-acids of zein (which otherwise would be discarded) to form tissue protein.⁵

In a similar manner the amino-acids of gelatin are utilized if supplemented by a protein rich in tryptophane and cystine. Even two incomplete proteins, if one contains an abundance of the amino-acids which the other lacks supplement one another. So, the biological value of two proteins given together may be much greater than the sum of their values when fed alone. Proteins which lack the same amino-acid (e.g., casein and phaseolin which are deficient in cystine) cannot of course supplement one another. The supplementary relations of proteins is evident in the chief natural foods: these all contain two or more proteins (see table 54). For example, in milk, the deficiency of casein in cystine is made good by lactalbumin which contains a relatively high percentage of this amino-acid. Also, though gliadin of wheat will not support growth, wheat itself will. The lysin-poor gliadin is supplemented by the other wheat protein, glutenin, which is rich in lysine. Maize contains, besides zein, the supplementary protein glutenin. These facts, obviously, are of fundamental importance in dietetics, especially in the economy of agricultural feeding. Cheaper foods can be fed and good nutrition promoted if due consideration be given to the supplementary relations of their contained proteins. Gelatin rich in lysine improves the nutritional value of wheat and oats, both relatively poor in this amino-acid. There is also a pronounced supplementary relation between the proteins of milk and those of oats and wheat.

⁵ It follows that a protein of high biological value, i.e., one which possesses an assortment of amino-acids closely resembling that in body protein, i.e., one which when fed alone shows little wastage of nitrogen, will have little supplementing effect.

some samples of very fibrous beef, for instance, may be little higher than that of white flour.

THE SUPPLEMENTARY RELATIONS AMONG PROTEINS

It does not necessarily follow that because a certain protein is inadequate for growth or even

TABLE 54*
Character of proteins in some common foods

FOOD MATERIALS	CHIEF KINDS OF PROTEIN PRESENT	COMPLETE OR INCOMPLETE
Nuts	Excelsin	Complete
Cheese	Casein	Complete (low in cystine)
	Lactalbumin	Complete
	Glutenin	Complete
Wheat	Zein	Incomplete (lacks lysine and tryptophane, low in cystine)
Eggs	Ovalbumin	Complete
	Ovotellin	Complete
Gelatin	Gelatin	Incomplete (lacks tryptophane and tyrosine; only a trace of cystine, high in lysine)
Lean meat	Albumin	Complete
	Myosin	Complete
	Casein	Complete (low in cystine)
Milk	Lactalbumin	Complete
Navy beans	Phaseolin	Incomplete (low in cystine)
Peas	Legumin	Incomplete (low in cystine)
Soy beans	Glycinin	Complete
	Legumelin	Incomplete
	Gliadin	Incomplete (lacks lysine)
Wheat	Glutenin	Complete

* From M. S. Rose, "Foundations of Nutrition."

for maintenance that it is worthless in nutrition. It is evident from what has been said in the preceding paragraphs that an incomplete protein can be utilized if its shortcomings in one or more of the essential amino-acids are made good by the addition to the diet of some other protein, rich in the elements which the first one lacked. Zein, for

amino-acids which have been found indispensable for rats are also essential dietary constituents for other mammals, including man. There are, however, certain minor species differences, the growing mouse, for example, can dispense with arginine in the diet, since, apparently, it can synthesize this amino-acid in greater amounts than can the rat. Glycine, which is a dispensable amino-acid for mammals is an essential dietary component for chicks. The chick, also unlike the rat, has no

capable of maintaining nitrogenous equilibrium. The nitrogen balance could not be maintained upon a diet completely lacking in lysine, whereas, histidine proved to be dispensable. The relation of arginine to human nutrition is somewhat ambiguous. Holt and his colleagues found that nitrogenous equilibrium could be maintained for ten days upon an arginine-deficient diet. The seminal fluid of the subjects showed a reduction in the number of spermatozoa. When arginine was

FIG. 230. Chart on left shows satisfactory growth of rat when 18 per cent of casein was present in the diet as the sole protein. With a smaller amount of casein—9 per cent—much less rapid growth ensued. That the insufficiency of the smaller amount of casein is essentially due to its relative deficiency in cystine is shown by the marked accelerating influence upon growth brought about by the addition of this amino-acid to the food containing 9 per cent of casein and the prompt retardation of growth which resulted from the withdrawal of cystine from the diet. Chart on right shows the favorable effect upon growth of supplementing a protein (zein), incapable of maintaining animals when it is the sole protein furnished in the diet, with a more "perfect" protein (lactalbumin). The portion of the lactalbumin used—4.5 per cent—was of itself insufficient for full growth. It evidently furnished the amino-acid groups which were lacking in zein. (After Mendel.)

ability to synthesize arginine. The essential or non-essential nature of a particular amino-acid, as well as the species differences, may possibly depend upon bacterial synthesis in the intestine. It has been found, for example, by Martin that rats fed a diet containing all the essential amino-acids fail to grow if succinylsulfazole is added to the food. The most suitable proteins for growth are those of animal origin and especially those which nature has provided for the nourishment of the growing animal, namely, lactalbumin (of milk)

added to the diet their number was restored to normal. These authors suggested that the degeneration of spermatozoa, which are very rich in arginine, furnished this amino-acid and thus permitted the nitrogen balance to be maintained. Tryptophane was found to be indispensable, the subjects developing negative nitrogen balances within a few days after having been placed upon a diet lacking in this amino-acid. Nitrogen equilibrium could not be maintained when valine, threonine, leucine, isoleucine or phenylalanine were lacking from the diet.

It seems that, generally speaking, the several

Tyrosine can be formed from phenylalanine. In rats deprived of *valine* grave nutritional defects develop which have been the subject of studies of Epstein and Rose. The animals become very sensitive to touch and show severe muscular incoordination, (e.g., staggering gait and circus movements) together with loss of appetite, emaciation and eventually death.

The amino-acid requirements for building new tissue (growth) are more exacting than those for repair (maintenance), i.e., for the maintenance of nitrogen equilibrium in the adult and the prevention of a loss of weight. Some amino-acids which

is added to the diet of which edestin is the sole protein, or cystine or methionine is added to the casein diet the other amino-acids in these proteins can be utilized and built into body tissue.⁴ Lysine is essential for maintenance as well as for growth, but for the former, relatively small quantities are required. Gliadin (of wheat), for example, which contains less than 1 per cent lysine is inadequate for growth even though fed in large quantities but is suitable as the sole source of protein in an adult. Zein, on the other hand, which is entirely lacking in lysine and contains little tryptophane is inadequate for either growth or maintenance. The

* Modified from Mitchell and Hamilton, "The Biochemistry of the Amino Acids," Am. Chem. Soc. Monograph Series No. 48, p. 191.

are essential for the growing animal can be dispensed with in the adult. Those necessary for both growth and maintenance are marked with an asterisk in the table on page 559. Even of these the level in the diet need not be as high for maintenance as for growth. The utilization of a protein deficient in one or other amino-acid is limited by that deficiency. For example, if edestin, which is poor in lysine, is the sole protein of the diet, the other amino-acids of which it is composed are utilized only in certain proportions limited by the lysine content. A large part of the remainder is discarded. Similarly the utilization of casein is limited by its methionine content. Now if lysine

Most of the work relating to the indispensability of the various amino-acids has been carried out upon rats. More recently, Holt and his colleagues have investigated this question in adult human subjects. Their results, in general, accord with those of animal experiments. Methionine, as the sole source of sulfur amino acids, was found to be

⁴ To make this point clear we may use as illustration the case of a type-setter who has lost a number of dies for, say, the letter A. He can continue to set type so long as his supply of A letters lasts, but when this is exhausted his work must cease though there is still a large number of other letters. His type-setting is limited by his supply of A letters.

supported. Also when the amino-acid deficiency is not too great, growth can be promoted by increasing the percentage of the incomplete protein in the diet (see table 53).

An essential or indispensable amino-acid is defined as one which cannot be synthesized in the body in adequate amounts for normal growth and nutrition and must therefore be supplied in the diet. Of the twenty-two amino-acids which have been identified as constituting protein material, eleven are indispensable for normal growth. They are as follows:²

- *Threonine [β -hydroxy- α -aminobutyric acid]
- *Valine
- Leucine
- *Isoleucine
- Arginine
- Lysine
- *Methionine
- *Phenylalanine
- *Tryptophane
- Histidine

Experiments in which it was shown that casein would not support growth unless fed in relatively large amounts or in smaller amounts and supplemented by cystine, led to the belief that this amino-acid was indispensable. The mistake was evidently the result of confusion with the other sulphur-containing amino-acid, methionine. The failure of growth on the low casein diet was due to this protein's inadequate methionine content, but this could be made good by the addition of cystine. In other words, cystine can substitute *in part* for methionine; cystine itself is not essential, for it can be *completely* replaced in the diet by methionine³ which can be converted to cystine in the body. Proof of the derivation of cystine from methionine was obtained by Tarver and Schmidt who fed animals methionine containing the radioactive isotope of sulphur (S^{35}) and later isolated isotopic cystine from their tissues. As mentioned of page 544, hemocystine combined with choline can, through transmethylation, substitute for methionine. *Arginine*, as mentioned on p. 545 can be synthesized in the body but not in adequate amounts for normal growth; it is therefore an essential constituent of the diet of young animals.

² Those marked with an asterisk are essential for both growth and maintenance.
³ An exception to this statement is concerned with the regeneration of plasma protein, for which (in dogs at any rate) cystine is essential; it cannot be replaced by methionine. Madden and associates).

and after the missing amino acid had been added to the diet. Rose's method consists in feeding a mixture of purified amino acids such as are found in casein. The effect upon growth was then determined after one or other amino acid had been omitted from the mixture.

THE ESSENTIAL IMPORTANCE OF CERTAIN AMINO-ACIDS FOR GROWTH AND MAINTENANCE

In 1907 Hopkins and Willcock found that when mice were fed upon a diet which contained zein (a protein of maize) as its sole protein, growth was arrested and the animals died in about 17 days. Zein is almost completely free from tryptophane. Yet, the addition of this amino-acid to the diet was not capable of promoting growth, and the survival period of the animals was extended to only 33 days. The addition of tyrosine was without effect since zein already contains this amino-acid in adequate amounts. It was shown by Osborne and Mendel that when lysine, which is completely lacking in zein, was added to the zein diet together with tryptophane, the animals grew

FIG. 229. Shows the indispensableity of lysine for growth. (After Mendel.)

normally and remained in good health (fig. 229). Lysine added alone was of no more benefit than tryptophane alone. *Gelatin*, like zein, is an incomplete protein. It lacks tyrosine and tryptophane and is very deficient in cystine. A diet which contains gelatin as its sole protein will not permit growth nor even maintain nitrogen equilibrium in an adult animal. When, however, the lacking amino-acids are added to the gelatin diet its defects are corrected.

Casein. Casein is deficient in glycine and has a low cystine content. If, however, casein be fed in sufficient quantity—about 18 per cent of the diet—or if cystine be added, normal growth results (fig. 230).

Edestin (a protein in hemp seed) is relatively poor in lysine as is also *gliadin* (of wheat) while *phaseolin* (of navy bean) is deficient in cystine and tryptophane. If these, or other incomplete proteins, are supplemented by adding to the diet the amino-acids in which they are deficient, growth is

tive value. Inferior proteins must be fed at higher levels. The relative values of several foods as given by these authors are shown below. The proteins of beef kidney head the list, the others are shown in order from left to right.

In order to know the value of a food as a source of suitable protein the quantity of protein which it contains as well as the latter's biological value must be considered. Thus a food may contain a poor protein in larger amounts or a first-class protein in small amounts. Again, in some foods the protein is both poor in quality and low in amount while in others both the quantity and quality of the protein are high. So we may take these two factors into consideration and speak of the *protein value* of a food. The quantity of protein in a sample of food is obtained by multiplying the value for its nitrogen content by 6.25 since pure animal food protein contains

was therefore $\left(\frac{40.1}{51.1} \times 100\right) = 79$ per cent.

A rat receiving a diet containing about 4 per cent of protein, ingested daily 56.9 mg. of nitrogen and excreted 27.6 mg. of nitrogen in the feces. Of the latter 21.7 mg. constituted metabolic nitrogen (p. 557). The unabsorbed N was therefore only (27.6 - 21.7 =) 5.9 mg., and the absorbed N (56.9 - 5.9 =) 51.0 mg. The daily urinary N was 48.6 mg. Of this, 37.7 was derived from the body tissues (estimated from urinary N on a nitrogen-free diet, p. 553). The total urinary nitrogen less this value for the endogenous nitrogen must represent the quantity of absorbed nitrogen which was excreted, that is, (48.6 - 37.7 =) 10.9 mg. is the quantity of absorbed nitrogen which had been wasted in metabolism. The absorbed nitrogen, as just stated, amounted to 51.0. So, (51.0 - 10.9 =) 40.1 mg. were retained in the body. The biological value of the dietary protein was therefore $\left(\frac{40.1}{51.1} \times 100\right) = 79$ per cent.

A method by which the nutritive value of a protein may be given numerical expression is employed by Mitchell. In this method, the value of the protein for repair (maintenance) or building of new tissue (growth) is given as a percentage of its *absorbed* nitrogen which is not lost in the urine, i.e., the percentage retained in the body. This is called its *biological value*. The animal is placed upon a basal diet complete so far as non-protein factors are concerned. In order that none of the protein shall be burned for energy purposes, the level in the diet is kept low, i.e., there should be no excess over that required for growth or maintenance. The following example from Mitchell will serve for illustration.

A rat receiving a diet containing about 4 per cent of protein, ingested daily 56.9 mg. of nitrogen and excreted 27.6 mg. of nitrogen in the feces. Of the latter 21.7 mg. constituted metabolic nitrogen (p. 557). The unabsorbed N was therefore only (27.6 - 21.7 =) 5.9 mg., and the absorbed N (56.9 - 5.9 =) 51.0 mg. The daily urinary N was 48.6 mg. Of this, 37.7 was derived from the body tissues (estimated from urinary N on a nitrogen-free diet, p. 553). The total urinary nitrogen less this value for the endogenous nitrogen must represent the quantity of absorbed nitrogen which was excreted, that is, (48.6 - 37.7 =) 10.9 mg. is the quantity of absorbed nitrogen which had been wasted in metabolism. The absorbed nitrogen, as just stated, amounted to 51.0. So, (51.0 - 10.9 =) 40.1 mg. were retained in the body. The biological value of the dietary protein was therefore $\left(\frac{40.1}{51.1} \times 100\right) = 79$ per cent.

In order to know the value of a food as a source of suitable protein the quantity of protein which it contains as well as the latter's biological value must be considered. Thus a food may contain a poor protein in larger amounts or a first-class protein in small amounts. Again, in some foods the protein is both poor in quality and low in amount while in others both the quantity and quality of the protein are high. So we may take these two factors into consideration and speak of the *protein value* of a food. The quantity of protein in a sample of food is obtained by multiplying the value for its nitrogen content by 6.25 since pure animal food protein contains

on an average 16 per cent of nitrogen. The use of this factor assumes, of course, that all the nitrogen in the food is protein nitrogen but, as mentioned in the footnote on page 557 a variable amount is present as non-protein nitrogen.

The value of individual amino acids were tested by Osborne and Mendel by feeding purified proteins known to be deficient in their amino acid constituents. Growth upon the deficient protein was observed before

It is rather surprising that wheat proteins stand so high; the results of other methods of investigation do not indicate such a superiority over the proteins of milk and beef, nor that barley and rye proteins are equal to those of beef muscle.

The determination of the minimal quantities of different proteins required for the maintenance of nitrogenous equilibrium in adult animals or of a positive balance (storage of nitrogen) in growing animals is also

That is, the wastage in digestion is 5 per cent or less. The digestibility of the proteins of nuts and fruits is low, that of the proteins of legumes and of potatoes is around 80 per cent (see table 52). The digestibility of wheat proteins is from 90 to 100 per cent thus approaching that for animal proteins.

(b) THE SUITABILITY OF A GIVEN PROTEIN FOR THE SYNTHESIS OF BODY PROTEIN. This depends upon the amino-acid constitution of the protein. It is obvious that the greater the proportion of amino-acids in the dietary protein which can serve for the construction of tissue protein, the greater will be protein's potential nutritive value. In other words, the more closely the amino-acid assortment in the food protein resembles that in body protein the less of the former need be furnished. A smaller proportion of the amino-acids will then be discarded to have their nitrogen eventually excreted in the urine, i.e., less of the food protein will be wasted.

Methods employed for estimating the nutritive values of proteins. Osborne and Mendel, employing rats, added a known amount of the protein to be tested, to a diet free from all other proteins, but adequate in other respects (i.e., one possessing the necessary energy value, minerals, and the vitamins then known). They expressed the nutritive value of the protein as the weight, in grams, gained by the animals per gram of protein fed, in the case of young rats (value for growth), or in the case of adult rats, the smallest quantity of the fed protein in grams, per gram of rat per week, necessary to maintain a constant body weight (value for maintenance). McCollum and associates also employed rats, feeding a basal diet of first class quality in all respects except that it lacked protein. The lack was made good by adding the protein to be tested, and the percentage of protein required to be added to the food mixture in order to promote normal nutrition gave an index of its nutritive value. The general state of nutrition of the animals, as indicated by rate of growth, fertility, care of young and longevity, was noted over a period corresponding to two-thirds or more of their life-span. On this basis, proteins were classed as "excellent," "good" or "poor." An excellent or first-class protein is one which "will support nearly optimum nutrition over periods approximating two-thirds or more of the normal life span of the rat when fed in amount corresponding to 9 per cent of the food-mixture." Nine per cent is therefore the critical level for a protein of the highest nutritive value.

Two factors must be considered in determining the nutritional value of a given protein: (a) its digestibility, i.e., the amount absorbed, and (b) its suitability for the construction of tissue protein.

(a) THE DIGESTIBILITY OF PROTEINS. Though by far the greater part of the nitrogen arising from the catabolism of amino-acids within the body is excreted in the urine, a small fraction is eliminated through the secretions of the digestive glands and intestinal mucosa. This, the so-called *metabolic nitrogen*, is estimated from the nitrogen of the feces upon a nitrogen-free diet. In a man it amounts to from 0.5 to 1.5 gram daily, varying in amount with the bulk (roughage) of the diet. In order, therefore, to determine the proportion of a given protein which has undergone digestion and absorption, the total nitrogen content of the ingested protein¹ is determined and from this value the nitrogen of the feces less that for the metabolic nitrogen is subtracted. Thus—

$$\text{Food N} - (\text{feces N} - \text{metabolic N}) = \text{absorbed N.}$$

The digestibility of the particular protein is then expressed as a percentage of the food nitrogen which has been absorbed into the blood. This percentage value is referred to as the *coefficient of digestibility*. For example, if the food contains, let us say, 10 grams of nitrogen and it is found that 9.5 grams have been absorbed the digestibility is 95 per cent. Digestibility in the sense just defined is quite different from the popular meaning of the term which refers rather to the subjective sensations accompanying digestion. Pork and veal, for example, are looked upon as indigestible types of meat, yet the percentage of their protein which is absorbed, i.e., their coefficient of digestibility, is high.

Proteins of animal origin have the highest digestibility which runs from 95 to 100 per cent.

¹ The total N in a sample of protein food is somewhat more than that actually present as protein-N. That is, a small part is present in the form of free amino-acids, their derivatives and other non-protein substances. Since much of the nitrogen in these forms is believed to be of definite nutritive value, no greater error is entailed in making the calculations upon the basis of the total food nitrogen than if a correction were made for their presence.

tion of urea, rather than the conversion of the deaminated residues to glucose is responsible for the specific dynamic action of protein. Lundsgaard found, for example, that though the administration of sodium acetate or sodium lactate was followed by only a slight increase in heat production, ammonium acetate or ammonium lactate caused a pronounced rise; even ammonium chloride caused a well marked increase in heat production.

The reactions responsible for the S.D.A. of protein are apparently situated in the liver and not in the tissue cells generally, since Wilhelmj, Bollman and Mann were unable to obtain any effect in hepatectomized dogs. Dock also found that after the administration of casein to rats the oxygen consumption of the hindquarters (muscular tissue) was 8 per cent greater than in the corresponding tissues of a control group, whereas the oxygen consumption of the abdominal viscera was 141 per cent greater.

The specific dynamic action of carbohydrate is thought to represent the energy liberated in excess of that required for the conversion of glucose to glycogen.

After a fast which depletes the glycogen stores, ingested glucose is oxidized in negligible amounts, yet it causes a pronounced specific dynamic action (Dann and Chambers).

The specific dynamic action of fat is ascribed to the increased concentration of fat in the tissue fluids and, as a consequence, to its more rapid oxidation ("plethora theory" of Lusk).

The glands of internal secretion appear to have no direct influence upon the S.D.A. of protein; the usual effect has been observed in a cretin with a basal metabolic rate 20 per cent below normal and it is not altered in hyperthyroidism. Thyroidectomy in animals is said, however, to reduce the S.D.A. of carbohydrate and fat. Cushing and Fulton found the S.D.A. of protein within the normal range in a number of cases of pituitary disease (hypopituitarism and acromegaly). Gaebler found it of normal value in hypophysectomized animals. In undernutrition the S.D.A. of all foods is increased. It is, according to some observers diminished in simple obesity (p. 609).

processes, i.e., to the contractions of smooth muscle of the alimentary canal or to the work entailed in the secretion of the digestive juices. This is proved by the following facts. Bones given to a dog, or agar agar, saline cathartics, water or meat extracts (which stimulate powerfully the gastric secretion) given to man, have no effect upon the heat production. Also, as already mentioned protein has no S.D.A. when new tissue is being laid down. On the other hand, the injection of certain amino-acids into the blood stream is followed by a specific dynamic effect.

The S.D.A. of protein has been shown to depend upon the following six amino-acids—*glycine*,

lowed by a specific dynamic effect. The S.D.A. of protein has been shown to depend upon the following six amino-acids—*glycine, alanine, leucine, glutamic acid, tyrosine and phenyl-alanine*. The last, as shown by Rapport and Beard, has the greatest effect of all. The action of glycine is greater than that of alanine but either of these exerts a smaller effect than tyrosine; the effect of leucine is slight. Until recently the specific dynamic effect of glutamic acid has been denied. The S.D.A. of a given quantity of meat equals that calculated from its content in these amino-acids. The other amino-acids investigated have no specific dynamic action.

The fundamental cause of the S.D.A. of protein is not altogether clear, though it is generally admitted that the amino-acids exert in some way a direct and specific stimulating effect upon the tissue cells, raising the latter's metabolism to a higher level, i.e., the combustion of the cells' own fuel material is increased. The extra heat is not due to the amino-acids themselves being utilized as fuel nor to the action of these materials in the unchanged state. It is in the intermediary reac-

tion of protein should be sought—possibly in the deamination process. Lusk suggests, however, that reactions involved in the conversion of the deaminated residues of the amino-acids to glucose and of glucose to glycogen are ultimately responsible for the extra heat production. These reactions are endothermic; in order to drive them, energy derived from an exothermic reaction is required. This energy is supplied by the oxidation of fuel materials by the tissue cells but an amount of energy is produced over that actually required. The excess appearing as heat constitutes the specific dynamic action. Since the R.Q. rises during the development of the S.D.A. the fuel undergoing combustion by the cells is thought to be glucose. These views have been criticized by Borsook and Winegarden who consider that from 25 to 60 per cent of the S.D.A. of protein results from the metabolism and excretion of nitrogen. The remainder of the heat production is attributed to the metabolism of carbon. There is a considerable body of evidence for the belief that the deamination of the amino-acids with the forma-

Calories respectively. The extra heat is generated by the combustion of body substance, so if loss of weight is to be prevented such an animal must be supplied with 130 Calories if his diet is protein; or if carbohydrates and fats are also consumed extra allowances must be made for the amounts of these substances which have been included. The extra heat resulting from protein food cannot be employed for the production of mechanical or other forms of energy. It is waste heat and is simply added to the heat produced by the muscular exertion. A diet very rich in protein is therefore unsuited to heavy muscular work. The S.D.A. of protein is an important factor, however, in the

The results of an experiment of Rapoport's which illustrates the utilization of the "waste heat" of the specific dynamic action of fat and glucose in exercise

regulation of body temperature (p. 629). With fat and carbohydrate the case is different, for the extra heat is harnessed in the performance of work. When exercise is undertaken upon either of these substances the heat due to their specific dynamic action is practically abolished, the extra energy being incorporated in the energy exchanges of the exercise (table 51).

When new tissue is being formed, i.e., when the nitrogen balance is positive, protein does not exert its usual specific dynamic action.

The cause of the specific dynamic action

Several explanations for the phenomenon have been offered. It is certainly not due to digestive

containing data from an experiment of Cathcart's illustrates this point.

Urine	7.78
1st day of starvation	7.43
1st day on cream (300 cc.), starch (400 grams)	3.58
2nd day on cream (300 cc.), starch (400 grams)	2.84

diet	

The nitrogen excretion upon a protein-sparing diet of this nature containing suitable proportions of carbohydrate and fat to meet the caloric requirements, represents the lowest level to which protein catabolism can be reduced. As just indicated, it is lower than the average excretion throughout a period of starvation. It is clear that none of the nitrogen excreted on the cream and starch diet shown in the foregoing table was derived from the breakdown of protein used for energy purposes since the necessary calories were supplied by carbohydrate and fat. The nitrogen excretion on such a protein-sparing diet is therefore an index of the inevitable disintegration of body protoplasm which occurs under ordinary physiological conditions. For this reason it was called, by Rubner, the "wear and tear" quota of protein metabolism. One of the lowest values reported for nitrogen excretion is that of Boothby and Sandiford, namely, 1.74 grams daily (0.024 gram per kilogram of body weight).

Carbohydrate exerts a specific sparing action quite apart from the fact that it furnishes energy and so relieves protein of the necessity of performing this duty, for the sparing effect exhibited by a given quantity of carbohydrate cannot be brought about by an amount of fat possessing double the caloric value. Carbohydrate when fed alone has a marked sparing action, whereas fat alone has little or no protein-sparing effect and a positive nitrogen balance cannot be established in man on a diet composed entirely of fat and protein. Nor will fat by itself, when given after a period of fasting, reduce the nitrogen excretion below that during the fast. Indeed, it actually increases the output of nitrogen. The increase may be related to the fact that fat, in the absence of carbohydrate, is incompletely oxidized; acetoacetic and β -hydroxybutyric acids appear and acidosis develops. A diet whose calories, up to 50 per cent or more, are derived from fat and the remainder from carbohydrate has, however, as great a protein-sparing action as one whose calories are derived from car-

bohydrate alone. Lactic and pyruvic acids, products of carbohydrate metabolism, are also protein-sparers to some extent. The sparing effect of carbohydrates can be demonstrated in the well-nourished animal as well as during starvation. When dogs in nitrogen equilibrium are given extra glucose, nitrogen is retained but the balance is established when the administration of glucose is stopped (Larson and Chaikoff). The difference between the sparing actions of fat and carbohydrate is not easily explained. According to one view (Landergeren) the specific sparing effect of carbohydrate depends upon the fact that glucose is vitally essential to the body and must be constantly supplied whatever the cost. If it is not available from outside sources or from the glycogen stores, tissue protein is broken down to yield materials from which it may be synthesized. Another more probable explanation of the peculiar sparing action of carbohydrate is, that it is used in the synthesis of the amino-acids which are incorporated into body proteins. According to this view the nitrogen resulting from the breakdown of tissue protein during fasting (or from tissue and food protein when the diet consists exclusively of protein and fat) is largely or entirely excreted. If, on the other hand, certain intermediary products of carbohydrate metabolism are available, e.g., pyruvic acid, etc., (p. 571) it is possible for amino-acids to be resynthesized. That is, nitrogen which would otherwise be wasted is retained.

THE SPECIFIC DYNAMIC ACTION OF FOOD

That the ingestion of food increases the heat production was known to Lavoisier. This effect of food in raising the metabolism above the basal level is called its specific dynamic action (S.D.A.). The heat production commences to rise within an hour after the food has been eaten, attains a maximum in about the third hour and is maintained at this level for several hours. The greatest specific dynamic action is excreted by protein food. When protein is fed alone to a fasting animal, in an amount possessing a heat value equivalent to the animal's basal metabolism, the heat production is raised 30 per cent or more above the basal level. Carbohydrate causes a rise of about 6 per cent and fat of 4 per cent. That is to say, when a quantity of protein, carbohydrate or fat having an energy value of 100 Calories is fed separately to an animal whose basal metabolism is 100 Calories daily, its actual heat production will be 130, 106 or 104

digest sufficient amounts of protein to satisfy his energy requirements. Under such circumstances he draws upon his stores of carbohydrates and fats, but after these have been exhausted the protein elements of his tissues are disrupted. The non-nitrogenous portions of the amino-acid molecules are burned to make up the calorie deficiency, and, as a consequence, quantities of nitrogen derived from food and body protein are excreted. It has been calculated that the human subject would have to consume, daily, some 8 pounds of meat—practically an impossible feat for a civilized man,—in order to furnish the necessary energy and maintain the body in nitrogen equilibrium. On the contrary, a carnivorous animal such as the dog which possesses a large capacity for the digestion of protein food⁶ thrives upon a diet composed entirely of lean meat. The Eskimos are also capable—according to Krogh—of consuming relatively enormous quantities of meat. On a mixed diet, as we shall see immediately, nitrogen equilibrium can be established on a very low protein intake.

PROTEIN SPARERS

Carbohydrates and fats are called *protein sparsers* since their presence in the diet relieves tissue protection of the necessity of furnishing energy. The nitrogen balance had been established, 350 grams of carbohydrate were withdrawn from the diet. The nitrogen excretion increased from 19.84 to 27.00 grams daily, the balance becoming negative. Also, the nitrogen excretion in the urine in starvation is nearly 3 times greater than that upon a diet, nitrogen-free, but of adequate energy value (i.e., one composed exclusively of fat and carbohydrate). The non-protein food has reduced the break-down of tissue protein. The following table

* The daily energy requirement of man is, say, 3000 Calories. Eight pounds of meat (3600 grams approximately) which is 20 per cent protein, has a caloric value of $\left(\frac{100}{20} \times 3600 \times 4.1\right) = 2900$. The energy expenditure of an average-sized dog, on the other hand, is around 600 Calories. It can consume in less than a minute 2 pounds (900 grams) yielding more than 700 Calories.

Example of adjustment of nitrogen balance to increased intake

TABLE 50*

established by simply feeding this quantity of protein nitrogen. It is found however that a considerably larger quantity is necessary. The reason for this is that the amino-acids are required by the body in different proportions from those present in the food protein. In order that the body shall obtain a sufficient quantity of suitable amino-acids for the replacement of its own protoplasm and for the manufacture of various secretions and other essential materials, a relatively large assortment must be available from which it can choose. Those not required are discarded. For this reason, equilibrium can be established upon a smaller quantity of animal protein, such as beef muscle which contains amino-acids more nearly in the same proportions as those in human body protein,

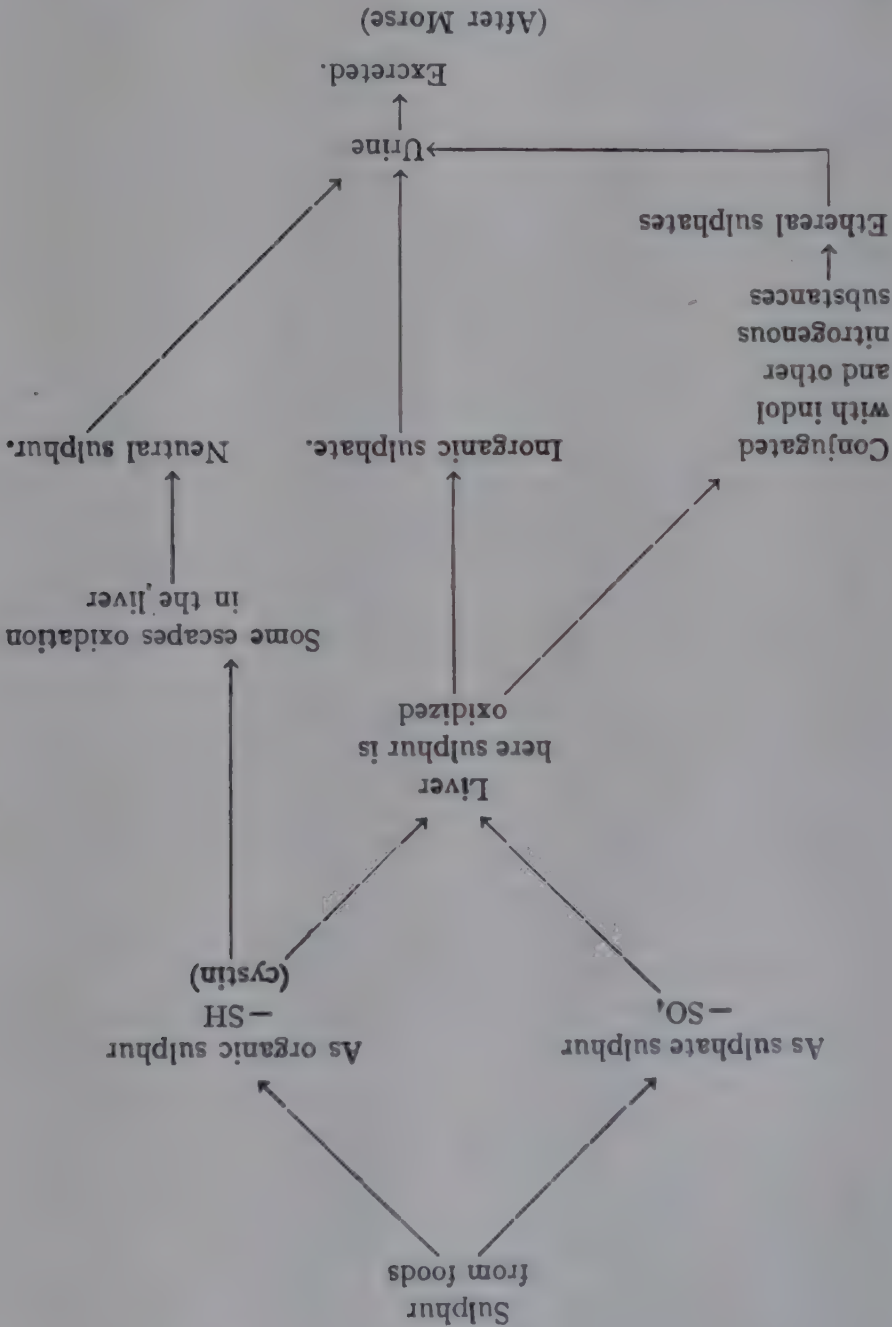

DAY	NITRO-GEN IN FOOD	NITRO-GEN IN FECES	NITROGEN "ABSORBED"	NITROGEN IN URINE	NITROGEN BALANCE

* Modified from H. C. Sherman, "Chemistry of Food and Nutrition," 4th edition.

rather than upon vegetable proteins. The wastage of nitrogen is less in the former instance. If the only protein in the food is one entirely lacking in certain essential amino-acids (lysine, histidine, etc.) the loss of nitrogen resulting from the breakdown of such amino-acids in the body's protoplasm cannot be replaced. A negative balance results no matter how much of the inferior protein has been fed (see p. 557).
The quantity of protein required to establish nitrogen equilibrium depends very greatly upon the content of the diet in the other two food principles—fats and carbohydrates. It is impossible, for example, to establish nitrogen equilibrium in man upon an exclusively protein diet; the excretion of nitrogen always exceeds the intake even though the individual ingests protein to his full capacity. The reason for this is that man cannot consume and

sufficient amount of protein to repair this so-called "wear and tear" his output and intake of nitrogen will balance, i.e., he will be in nitrogen equilibrium. If his diet contains protein in excess of this amount the nitrogen not employed for repair is excreted and nitrogen equilibrium maintained. In starvation or on a low protein intake, on the other hand, the individual continues to excrete nitrogen derived from the dissolution of

the hair, sweat, saliva, etc., is negligible). The amounts of nitrogen excreted daily in the feces and urine, respectively, average 1.3 and 13 grams. The nitrogen of the feces is in part unabsorbed through the intestinal wall. When the intake and output are equal, the body is said to be in *nitrogen equilibrium*. When the intake exceeds the output the body is in *positive nitrogen balance*—nitrogen

his own protoplasm, and so goes into negative balance. In children, in adults recovering from wasting diseases or undergoing muscular training, and in pregnant women, the body, if the protein intake is liberal, does not excrete as much nitrogen as it receives. Nitrogen is retained for the manufacture of new tissue. The daily excretion of nitrogen of a man of average weight upon a nitrogen-free diet amounts to about 3 grams. It might be thought that nitrogen equilibrium could be re-

is being retained. If the reverse is the case, i.e., the output exceeds the intake, the balance is said to be *negative*—the body is losing nitrogen. When the nitrogen of the food is increased a greater quantity for a time thereafter is retained, but the balance soon becomes adjusted to the higher intake and gradually returns to its original value (table 50). The healthy adult requires protein to replace the inevitable loss of tissue protein. When given a

The quantities of inorganic and ethereal sulphates in the urine vary with the protein level of the diet; the neutral sulphur is influenced to a less degree. For this reason the two former partitions of the urinary sulphur were considered by Folin to represent food (exogenous) sulphur while the neutral sulphur was taken to be derived mainly from body protein (endogenous sulphur) (see p. 550). On a diet of meat or during prolonged starvation the ratio of sulphur to nitrogen in the urine is about 1 to 14, i.e., for every gram of sulphur there are approximately 14 grams of nitrogen. This is approximately the S:N ratio found in muscular tissue. A graphic summary of sulphur metabolism is shown on page 552.

As a result of the excessive production and absorption of putrefactive products the excretion of ethereal sulphates is increased in acute intestinal obstruction. They are also increased in carcinoma

TABLE 49

Concentrations of different forms of sulphur in whole blood and serum (After Denis)

The inorganic sulphur of blood is elevated in renal insufficiency, intestinal obstruction and leukemia.

of the liver. Chronic constipation, however, exerts little or no influence upon the excretion of these substances (see p. 507).

The excretion of neutral sulphur is increased in the rare metabolic anomaly known as *cystinuria* and in cases of *melanotic sarcoma*, when an abnormal sulphur-containing pigment appears in the urine.

The non-protein sulphur of blood. The sulphur of blood, other than that present as a constituent of protein, amounts to from 3 to 5 mg. per 100 cc. The concentrations of the three forms is given in table 49.

AMMONIA (SEE PAGE 391)
NITROGEN BALANCES

The difference between the nitrogen taken in the food and that excreted in the feces and urine is spoken of as the nitrogen balance (that lost in

- B. *Inorganic*
Potassium, sodium and magnesium sulphates.

THE DISTRIBUTION OF SULPHUR IN THE BODY. Sulphur is contained in the ordinary tissue proteins; in hair, horn, feathers, etc.; in mucin, as mucosin-sulphuric acid and chondroitin-sulphuric acid; in certain glycoproteins of tendons, vitreous humor, cornea and connective tissues; in glutathione and insulin; in the taurocholic acid of bile; as sulphocyanate in saliva; in ergothioneine, a compound found in red corpuscles; in certain pigments (melanins, urochrome), and in nervous tissue as sulpholipoids. Inorganic sulphates are contained in the body fluids generally.

The loss of sulphur from the body occurs in the shedding of hair, nails, etc., in the bile, saliva and gastro-intestinal secretions. The great bulk of the sulphur loss, however, occurs through the kidneys.

The history of sulphur in the body. The sulphur liberated in the catabolism of dietary protein is largely converted to inorganic sulphates. A part of the inorganic sulphate derived from this and other sources becomes conjugated in the liver with substances produced in the intestine by the bacterial decomposition of protein to form *etheral sulphates* (p. 507). The latter are excreted in the urine. The products of bacterial action, among which are phenol derived from phenylalanine and tyrosine, and indole and skatole from tryptophane, possess toxic properties. Their excretion as etheral sulphates constitutes a detoxicating mechanism. When the detoxicating function of the liver is depressed as a result of hepatic disease, these toxic substances are excreted by the kidney in abnormal amounts in the free state.

Urinary sulphur. The total urinary sulphur is made up of the following:

- (1) Inorganic sulphur (85 to 90 per cent). Compounds of sulphuric acid with Na, K, Ca and NH₄.
- (2) *Ethereal sulphate sulphur* (6 to 8 per cent), e.g., potassium and sodium salts of indoxyl sulphuric acid. The latter is known as indican.
- (3) *Neutral sulphur* (4 to 6 per cent) e.g., sulphur-containing amino-acids, urochrome, thiosulphates, thiocyanates, taurocholic and oxyproteic acids.

is from 20 to 26 for the majority of normal men and from 14 to 22 for women. Its value depends upon the muscular development of the individual; the sex variation being due presumably to the different relative amounts of fatty and muscular tissues of male and female bodies. Athletic women for this reason have a coefficient as high as or higher than a man of obese build and poor muscular development.

THE METABOLISM OF SULPHUR

Sulphur enters the body mainly as a constituent of the amino-acids *cystine* and *methionine*. Food also contains inorganic sulphates, e.g., sodium and potassium sulphates, small amounts of sulphur in the form of sulpho-lipoids (sulphatides), and sulphur combined in certain glycoproteins as mucotin-sulphuric acid and chondroitin-sulphuric acid. Sulphur in inorganic form cannot be used in the construction of body protein. Practically speaking, the body is dependent for its sulphur supplies upon the two sulphur-containing amino-acids mentioned above. Food sulphur may be summarized as follows:

A. Organic
(1) Protein sulphur

(a) Sulphur-containing amino-acids, cystine and methionine.

generative changes occur in the muscles. The disease is accompanied by a high degree of creatinuria and a reduction in the excretion of creatinine. The thymus is frequently enlarged. Administered creatine is practically all excreted as such. Death results from involvement of the respiratory muscles. Very promising results have been reported following the treatment of this condition by the oral administration of glycine. Of 12 cases treated by Boothby with glycine and ephedrin, a drug which also has a favorable influence upon the disease, 10 were improved, and 4 of these markedly improved. Glycine apparently exerts no beneficial effect upon progressive muscular dystrophy. In 1934 Walker described a dramatic improvement in a case of myasthenia gravis produced by giving phosostigmine (eserine). More recently "Prostigmin" has been used in a series of cases with even more satisfactory results. The almost immediate improvement in the condition of the patients suggests that the drug acts specifically upon the neuromuscular mechanism attacked by the disease. The effects of one injection persist for eight hours or so. As discussed elsewhere (p. 946) the physiological effect of phosostigmine and presumably of "Prostigmin" is to inhibit the action of the esterase which is responsible for the destruction of acetylcholine liberated at certain nerve terminals, but the exact manner in which this agent exerts its beneficial effect in myasthenia gravis is unknown. In this disease the blood cholinesterase is not higher than the normal. On the other hand, a fall in the cholinesterase activity of the blood after prostigmine administration has been demonstrated. A delayed and more prolonged improvement in muscular power of these patients follows the injection of choline esters (acetylcholine and acetyl-β-methylcholine). Potassium is also reputed to exert a salutary effect.

Creatinine excretion as an index of muscle metabolism

The daily output of creatinine in the urine is constant for the individual, amounting to from 1.5 to 2.0 grams for men and from 0.8 to 1.5 grams for women. This corresponds to about 2 per cent of the creatine of the body. Unlike the excretion of urea, which is derived largely from exogenous sources, the creatinine output is practically independent of the protein level of the food. This is evident from table 48. The creatinine excretion is therefore considered to be an index of the magnitude of the metabolism of the tissues and especially of muscle. The daily output of creatinine is extraordinarily constant for the individual; it is not influenced by ordinary exercise or by the urine volume. The creatinine coefficient—

$$\frac{\text{milligrams creatinine excreted per day}}{\text{body weight in kilograms}}$$

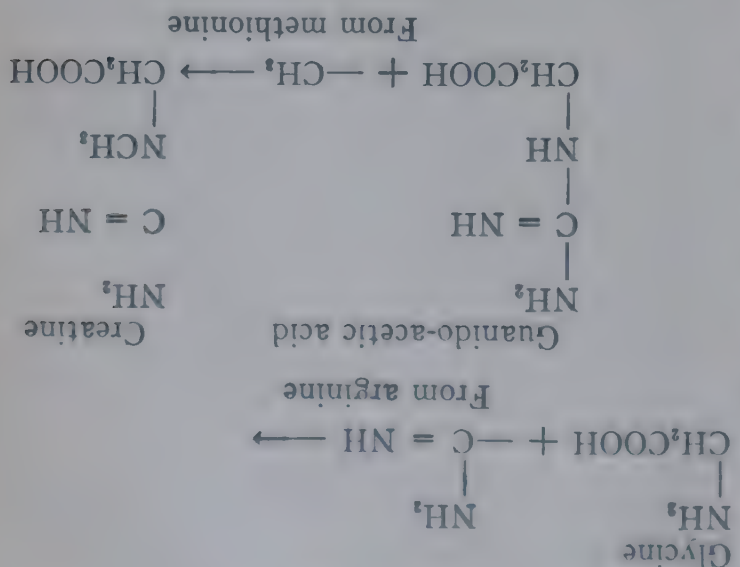

* Or creatine + creatinine, when creatinuria exists.

that glycine, which is an indispensable amino-acid for chicks, can be replaced in the diet of this species by creatine. These results pointed to arginine, guanido-acetic acid, and especially glycine as precursors of creatine.

The subject of creatine synthesis has been clarified recently through a number of experiments in which isotopes were used as markers to identify the particular substance under investigation after it had been absorbed. The administration of isotopic glycine (i.e., heavy nitrogen, N^{15} , incorporated in the glycine molecule) was shown by Bloch and Shoenheimer to give rise to creatine with a high concentration of the nitrogen isotope. Of all the other amino-acids investigated by this method, arginine alone was found to be a primary precursor of creatine. The isotope N^{15} was incorporated into the amidine part ($NH_2-C=NH$) of the arginine molecule. When the isotopic arginine was fed, the creatine isolated from the tissues of the animal was found to contain the isotope in this part of its molecule. The researches of du Vigneaud and of Borsook and Dubnoff show clearly that the methyl group of creatine is furnished by methionine. The former worker prepared methionine in which the three hydrogen atoms of the S-methyl group were present as the isotope H_3 (deuterium). When this was fed and the creatine of the animals' bodies determined, the isotope concentration indicated that nearly 70 per cent of the methyl groups of the creatine molecule had been derived from methionine. Borsook and Dubnoff incubated liver slices with guanido-acetic acid which they found was slowly converted to creatine, the conversion being hastened by the addition of methionine. Guanido-acetic acid is apparently an intermediary in the synthesis of creatine in the body; when the isotopic form of this compound is fed isotopic creatine is formed. The conclusions to be drawn from these experiments are that arginine, glycine and methionine enter into the synthesis of creatine but that other amino-acids do not serve as precursors.² The first reaction, it appears, is between the amidine part of arginine and glycine with the formation of guanido-acetic acid, arginine furnishing the amidine group of the latter. The guanido-acetic acid then under-

² The views of Beard and his associates, though not generally accepted, should be referred to here. These investigators maintain that almost any amino-acid as well as urea and other nitrogenous substances can give rise to creatine, and that creatinine is not derived from creatine but that the latter is formed by the hydration of creatinine.

goes methylation by the transference of the methyl group from methionine. Thus—

The site of creatine production is not known definitely but it is probably in the muscles. These also in all probability are the site of creatine-creatinine transformation (by dehydration). Mann and Magath found that removal of the liver was without effect upon creatinine production. The creatine which gives rise to urinary creatinine is derived very largely from the phospho-creatine of muscle.

Creatine is not, as was held by some authorities in the past, simply a waste product of protein metabolism like urea. If, for example, a large dose of creatine is fed the greater part or the whole is retained in the body.³ Creatinine, on the other hand is purely a waste product. Up to 80 per cent or more of the amount can be recovered unchanged in the urine. The investigations of recent years into the chemistry of muscular contraction have revealed the essential importance of creatine (as phosphocreatine) in the contractile process (p. 614).

It is appropriate to mention here the results obtained with glycine in the treatment of *myasthenia gravis*. This condition, as its name implies, is a condition of profound weakness of the muscles, those of the eyes, face and throat being, as a rule, involved first. Collections of lymphocytes (lymphorrhages) and degeneration of ingested creatine is also demonstrable in man.

either sex under the following conditions; high protein diet, starvation, carbohydrate deprivation, diabetes, wasting diseases and fevers, exophthalmic goiter and in certain muscular dystrophies. The creatinuria in all of these conditions except the last is probably due to an increase in the normal catabolism of muscular tissue, the liberation of creatine occurring more rapidly than its conversion to creatinine. Protein food, for example, has a stimulating effect upon metabolism (p. 554), while in wasting diseases, fevers, etc., tissue breakdown is accelerated. Carbohydrate deprivation probably acts indirectly in that its sparing effect upon protein catabolism is absent. In the muscular dystrophies, e.g., myasthenia gravis, progressive muscular atrophy, amyotonia congenita, anterior poliomyelitis, etc., the urinary creatine is probably derived from the degenerating muscle fibers; the muscles also appear to be defective in their power to store creatine. The creatinuria of normal children has received no satisfactory explanation; it is said to be due to an increased production of creatine, induced in some way by the growth impulse, and also probably to a low capacity for creatine storage of the undeveloped muscles. Another possibility is that children have a relatively low power to convert creatine to creatinine (Hunter).

The origin of creatine and of creatinine

Creatinine is undoubtedly derived from creatine but there has been much uncertainty concerning the latter's origin. One or other of the substances to which its chemical formula suggests a relationship, e.g., guanidine, glycine, arginine, histidine, betaine or choline, has been considered as a possible precursor. The opportunity afforded by the creatinuria of muscular dystrophies has been taken advantage of by Brand and his colleagues in the investigation of this question. Various amino-acids and other guanido-compounds were fed to patients suffering from such disorders; ingested glycine, or gelatin which is rich in this amino-acid, causes a pronounced rise (40 per cent) in the creatine excretion of these patients but not of normal persons. The proportion of ingested creatine which is retained is also much less than the normal (*creatinine tolerance test*). Arginine and guanido-acetic acid (glycocycamine) were also effective. Feeding benzoic acid, which drew upon the body's glycine store for detoxication purposes (p. 391) caused a decrease in the creatine excretion. The importance of glycine in creatine synthesis is emphasized by the observation of Almqvist and Meckb

is the anhydride of creatine. Its molecular constitution is shown by the following formula

Distribution of creatine and creatinine

There are about 120 grams of creatine contained in the adult human body. Of this 98 per cent is contained in the muscles and 1.5 per cent in the nervous system. The remaining 0.5 per cent is distributed throughout the other organs of the body; of these, the testes contain it in highest concentration. The skeletal and cardiac muscles and the gravid uterus are a great deal richer in creatine than the smooth muscle of the gastrointestinal tract and elsewhere. About 80 per cent of the creatine in muscle is combined with phosphoric acid as *phosphocreatine* (p. 614). Of the striated muscles, the rapidly contracting, pale type contain more than the slowly contracting red variety (p. 824).

Creatinine is present in muscle in much smaller amounts. One hundred grams of skeletal muscle, for example, contains 200 to 300 mg. of creatine and only 10 mg. of creatinine. The creatine of whole blood amounts to from 3.5 to 5.0 mg. and the creatinine to about 2.5 mg. per 100 cc. By far the greater part, if not all, of the creatine is contained in the corpuscles. The creatinine is about equally distributed between cells and plasma.

Excretion of creatine and creatinine

Creatine is normally absent from the urine of men, but is present in the urine of male and female children up to the age of puberty and frequently in the urine of women. The significance of these sex differences is not evident. In non-pregnant women the *creatinuria* is intermittent but is not related to menstruation. During pregnancy creatine is present continuously in the urine. This may be related to the high creatine content of the uterus. For two or three weeks after child-birth the quantity excreted is even higher than during pregnancy. Reduction in the muscular mass of the uterus (involution) may account in part for the high output during the puerperium, but that uterine involution is not the chief cause is shown by the fact that it occurs although Caesarian section and removal of the uterus have been performed. Creatine also appears in the urine of

tissue leads to the production of urea. Urea is very widely distributed throughout nature, being a constituent of the body fluids of the lowest forms of animal life. It is also found in plants. For this reason its formation in animals might be thought to be a function common to all tissues. But the observations of Mann and his colleagues seemed to show that in dogs urea formation is exclusively an hepatic function. After complete removal of the liver the formation of urea ceases, so that the concentration in the blood and urine falls progressively, as does also the urinary ammonia. If the kidneys as well as the liver are excised there is no accumulation of urea in the blood though the amino-acid concentration rises. Also, after the injection of glycine or alanine into the hepatectomized animal, in contrast to the result obtained in the normal animal, the concentration of the injected amino-acid rises in the blood and urine, and there is no evidence of urea production. That these results in dogs apply to man is indicated by the observation of Rabinowitch. He has reported that in a case of extensive damage to kidneys and liver (acute yellow atrophy) the excretion of urine was almost suppressed yet the blood was urea-free. The appearance of leucine and tyrosine in the urine in acute yellow atrophy of the liver may also be ascribed to the failure of deamination of these amino-acids. Nevertheless, though the liver undoubtedly plays the predominant rôle in the production of urea, certain other tissues may share to some degree in its manufacture. Graham and associates found, for example, that the active mammary gland produces not inconsiderable amounts.

CREATINE AND CREATININE

Creatine ($C_4H_9N_3O_2$) (methyl guanidine-acetic acid or methyl-glyco-cyamine) has the following structural formula

From a study of the above formula it will be seen that from a chemical viewpoint creatine may be looked upon as a derivative of glycine, of guanidine or of guanidine-acetic acid. It is also related to arginine and probably to choline. It is readily converted to creatinine.

Creatinine, $C_4H_7N_3O$ (methyl glyco-cyamidine)

(2) The addition of a second molecule of ammonia to citrulline with the production of arginine. Therefore, the production of urea from ammonia and carbonic acid may be represented thus

There is probably at least one mechanism of urea production other than that dependent upon the arginine-ornithine cycle. Leuthardt found, for example, and his findings have been confirmed by Bach, that glutamine, ammonia and carbon dioxide form urea in the absence of ornithine. Indeed, some now doubt that the importance which has been attached to the ornithin cycle in the production of urea is fully justified (see Trowell, and Gornall and Hunter).

On an ordinary mixed diet from 80 to 90 per cent of the urinary nitrogen is urea-nitrogen. The absolute amount of urea-nitrogen excreted daily is usually from 9 to 13 grams (20 to 30 grams of urea). Minimal amounts are also excreted in the sweat (p. 626), salivary, intestinal and mammary secretions. The urea-nitrogen varies with the protein content of the diet. Upon a low protein diet the output may be as low as 2 grams and on a diet rich in protein over 25 grams. The value of urea-N is therefore taken as an index of the magnitude of the catabolism of food protein (exogenous metabolism, see table, p. 550).

The blood contains from 8 to 15 mg. of urea-N (18 to 35 mg. urea) per 100 cc. Urea is readily diffusible and is found in about the same concentration in the various tissues and other fluids, e.g., lymph, bile, cerebrospinal fluid and pancreatic juice, as in blood. The kidney, however, is an exception since it contains some 150 to 200 mg. of urea per 100 grams of tissue. We have already seen that the urinary ammonia is formed from urea and amino-acids in the kidney (p. 391).

THE SITE OF UREA PRODUCTION. It has long been known that the liver is an important site of urea formation. Perfusion of the liver with amino-acids or their addition to sliced liver

THE END PRODUCTS OF PROTEIN

METABOLISM UREA

The great proportion of the nitrogen released by the catabolism of the amino-acids appears in the urine of man, mammals, amphibia and fish as urea. In birds and reptiles, on the other hand, the chief end product of protein breakdown is *uric acid*. In man the latter is derived from the metabolism of the purines (p. 565). Urea is formed directly (i.e., without preliminary deamination), from *arginine*, which is hydrolyzed by the action of an enzyme—*arginase*—into *urea* and *ornithine*. Arginase is present in the liver of mammals but not in that of birds. The reaction may be represented thus

It is only within recent years that the importance of this mechanism in the production of urea has been realized and its details disclosed. It has been thought to account for the greater proportion of the urea formed in the body. When ornithine was incubated with slices of liver in the presence of ammonia and carbonic acid, large amounts of urea were formed. It is supposed that the ornithine combines with the ammonia and carbonic acid to form arginine which in turn is hydrolyzed by arginase into urea and ornithine. Thus it appears that arginine serves as an intermediary in the production of urea from the ammonia supplied by the other amino-acids. The ornithine liberated by the decomposition of arginine is used over again. Ornithine thus acts after the manner of a catalyst to facilitate urea production.

According to Krebs and Henseleit, the formation of arginine from ornithine occurs in two steps. (1) The formation of a substance called *citrulline* by the addition of a molecule each of ammonia and carbon dioxide to ornithine.

It was shown by Schoenheimer and his associates, using isotopic amino-acids, that dietary nitrogen was constantly and rapidly being incorporated into plasma proteins and into the proteins of liver, kidney and intestinal tract as well as, but more slowly, into the proteins, including hemoglobin, of the red cells. Furthermore, nitrogen is continually being exchanged between the various tissues. In the new theory originally proposed by Borsook and Keighley, protein metabolism is conceived as a dynamic mechanism in which breakdown and resynthesis proceed hand and hand, dietary protein replacing tissue nitrogen and the nitrogen of different organs undergoing continuous interchange. Even in the starving animal tissue protein does not undergo catabolism alone, but is being continuously resynthesized, new protein being formed in one tissue from nitrogen derived from another.

Protein storage—labile protein

Though it is accepted beyond all question that fat and carbohydrate are stored, it was not the belief that the body accumulated reserves of protein. (The increase in body protein which occurs during growth, pregnancy or athletic training cannot be considered as protein storage in the ordinary sense.) It has been shown, however, that protein storage also occurs. During starvation or upon a non-protein diet this *deposit protein* or *labile protein* is drawn upon. When protein is fed after a period of protein deprivation, retention of nitrogen occurs as a result of the reaccumulation of the protein stores. After these have been replenished the quantity of nitrogen excreted in the urine again balances that taken in the food. There is thus a lag in the establishment of nitrogen equilibrium in changing from one protein level to another. All organs and tissues including the blood plasma apparently contain protein in this form, a form which is not an intimate constituent of tissue structure and can be quickly mobilized upon demand. The plasma proteins are also thought to constitute a reserve store of protein upon which the body can draw during a period of protein starvation. According to Boothby and associates, the myxoedematous swelling characteristic of hypothyroidism (p. 673) is due to an increase in the quantity of deposit protein. The excessive deposit is broken down under the influence of thyroxine. The latter also reduces the quantity of deposit protein in the normal subject.

acid, alanine and arginine. The perfusion experiments just mentioned suggest that alanine may be synthesized from the derivatives of carbohydrate metabolism plus the ammonia which would otherwise be excreted as urea. Other more complex amino-acids, e.g., tryptophane, histidine, etc. (p. 542) contain special groupings which cannot be formed in the body. They are therefore essential constituents of the diet (p. 559). If, however, the special groups are supplied, as in the form of the keto- or hydroxy-acid, the corresponding amino-acid can in some instances be formed.

THE CLASSICAL AS OPPOSED TO THE MODERN VIEW OF PROTEIN METABOLISM

The classical theory of protein metabolism as proposed by Folin has held the field for many years. It was based upon the urinary excretion of nitrogen. Folin was pointed out that under widely altered intakes of nitrogen the quantities of creatinine and neutral sulphur excreted in the urine remained remarkably constant, whereas the excretion of urea varied in amount. Creatinine and neutral sulphur were thought to be derived from the "wear and tear" of body tissue and were taken as an index of *endogenous* protein metabolism. Urea, on the other hand, was believed to be derived solely from the catabolism of dietary protein and was referred to as the *exogenous* quota of protein metabolism. Several facts, discovered chiefly through experiments with isotopic nitrogen (N^{15}) used as a "tracer," are not in accord with Folin's theory. The body structure is not like a machine, the composition of whose parts remains fixed and unchanged except for a certain loss from wear and tear which is repaired from dietary material, but is constantly in a state of flux. It has been shown, for example, that when amino-acids containing isotopic nitrogen are fed to an animal in nitrogen equilibrium only small quantities of isotopic nitrogen appear in the urine, whereas, a relatively large amount (about half) can be recovered from the tissues. In other words, the dietary nitrogen had replaced catabolized tissue protein whose nitrogen was excreted in the urine. The nitrogen derived from tissue protein, thus, far exceeded in amount that which the classical theory attributes simply to wear and tear. It has also been found, contrary to expectations, were creatinine and neutral sulphur excretion an index of endogenous protein catabolism, that increasing the metabolic rate or of the endogenous protein catabolism does not increase significantly the urinary excretion of these

THE SYNTHESIS OF AMINO-ACIDS

That the body tissues, given the necessary amino-acids, can link them together and so synthesize protein is, of course, unquestioned. The extent to which the amino-acids themselves can be synthesized is a more difficult question to decide. Undoubtedly the body is able to synthesize glycine—the simplest amino-acid. For example, milk proteins contain no more than 0.1 to 0.3 per cent of glycine, yet from 100 grams of the former the suckling animal can build up 78 grams tissue protein containing 2.5 grams of glycine (Magnus-Levy). Also, the liver and kidney detoxicate benzoic acid by combining it with glycine to form hippuric acid which is excreted in the urine. When large quantities of benzoic acid are fed, the glycine in the excreted hippuric acid is greater in amount than that which could have been supplied preformed from body tissue. Analogous experiments with the detoxication of phenylacetic acid indicate that glutamic acid can also be synthesized. The mode by which synthesis of the amino-acids takes place is obscure. Experiments suggest, however, that synthesis can occur from α -keto acids or hydroxy-acids and ammonia by a process of reduction. Thus

$$R \cdot CH_2CO \cdot COOH + NH_3 \rightarrow R \cdot CH_2COHNH_2 \cdot COOH \rightarrow R \cdot CH_2COHNH_2 \cdot COOH + H_2O$$

ketonic acid hydroxy-acid amino-acid

Embsen found that alanine was formed by the surviving liver perfused with blood to which the ammonium salt of pyruvic acid had been added. Phenylalanine and tyrosine were also formed when the liver was perfused with the ammonium salts of the corresponding ketonic acids. Even the addition of ammonium chloride to the fluid perfusing a glycogen-rich liver resulted in the production of alanine. The latter also followed perfusion with ammonium lactate. Furthermore, it was shown by Knoop that when γ -phenyl- α -keto-butyric acid was administered to dogs the corresponding amino-acid appeared in the urine, while the experiments of Cox and Rose and of Sherwin and their associates indicate that histidine, an essential amino-acid, can be formed in the body when imidazole pyruvic acid or imidazole lactic acid is fed. The synthesis of arginine has also been demonstrated by Rose and his colleagues.

To sum up: it is established that glycine can be synthesized from precursors already present in the body. The same may also be said for glutamic

peptides) of the injected protein are utilized by the tissue cells.

THE FATE OF AMINO-ACIDS AFTER ABSORPTION

DEAMINATION. Those amino-acids which are not required intact for building body protein, for the manufacture of hormones or other secretions, are broken up. The incombustible amino group (NH_2) is split from the amino-acid molecule and the ammonia so produced is combined with carbon dioxide to form urea (p. 546). This is excreted in the urine. The fatty acid residue may either undergo oxidation, and thus furnish energy to the body, or be transformed into glucose. The glucose may be burned or be stored as glycogen, or again it may be transformed into fat. Not all amino-acids, however, are sugar or glycogen formers. Those which play this rôle are *glycine, alanine, aspartic, glutamic and hydroxyglutamic acids, serine, cystine, arginine and proline*. With the exception of arginine and proline these are all straight chain amino-acids with less than six carbon atoms. The quantity of these amino-acids present in 100 grams of protein is sufficient to form some 58 grams of glucose.¹ A depancreatized or phloridzinized dog, for instance, or the subject of severe diabetes, though upon a carbohydrate-

¹ Since different proteins contain varying amounts of sugar-forming amino-acids, this is an average figure. It was arrived at by calculation from the proportion of glucose (dextrose) to nitrogen in the urine—the so-called G:N (or D:N) ratio—in phloridzinized dogs fed exclusively upon protein or during a period of starvation. Lusk found the G:N ratio under such circumstances to be 3.65:1. The nitrogen of the urine is derived, of course, practically entirely from protein. The urinary glucose of an animal under the influence of phloridzin and whose glycogen stores have been exhausted is also assumed to be derived exclusively from protein. Now each gram of urinary nitrogen represents catabolism of 6.25 grams of protein. Therefore with a G:N ratio of 3.65:1 every 3.65 grams of glucose secreted indicates the conversion of 6.25 grams of protein. So

$$\frac{3.65}{6.25} \times 100 = 58 \text{ per cent}$$

In diabetic (depancreatized) animals during starvation or upon a protein diet the G:N ratios obtained by different observers vary widely. Minkowski's figure of 2.8:1 is most usually quoted (this would indicate the conversion of 45 per cent of protein to sugar). Macleod and his associates, however, have obtained ratios in depancreatized dogs after the withdrawal of insulin as high as 6:1 in some experiments, and less than 2:1 in others. The ratio did not show a constant value, either in different animals or in the same animal at different times. They therefore seriously question the reliability of the G:N ratio as an index of the extent of the protein to glucose conversion, and consider that protein is not the only source of the urinary glucose.

proteins contained in these substances, result in cutaneous eruptions and sometimes localized edema. Minute amounts of the protein apparently enter the blood stream in an unchanged or partially digested state. Asthma, hay fever and other allergic conditions (see also p. 366) have been traced to foreign proteins (pollen, cat or horse hair, feathers, etc.) entering the body through the respiratory passages.

Most proteins introduced directly into the blood stream or absorbed unchanged from the intestinal tract are utilized to a very limited extent or not at all, and may be toxic. The same may be said for proteoses and peptones. Homologous plasma protein is a notable exception. Whipple and his associates found that dogs could be maintained in nitrogenous equilibrium by the intravenous injection of plasma from other dogs as the sole source of protein. A suitable assortment of amino-acids, such as an hydrolysate of casein supplemented by cystine and tryptophane, injected intravenously, is capable of maintaining an animal in nitrogenous equilibrium. It is possible that a solution of gelatin or of isinglass suitably supplemented with the missing amino acids might be used.

It is the general belief that the tissues are unable to utilize protein degradation products larger than single amino-acids, but must receive their building materials already separated into single "stones" or "bricks", for the amino-acid assortment in the ingested or injected protein will ordinarily not be identical with those composing the tissues of the animal, and therefore cannot be built as a group into its body protein. On the other hand, the reduction of all food protein to its amino-acid constituents enables the cells to choose assortments peculiar to their own structure. Generally speaking, this conception is probably true, but the experiments of Howland and Hawkins suggest the possibility that it is not invariably under all conditions. They found that homologous plasma protein injected intravenously into dogs disappeared from the blood stream within 24 hours, yet there was no detectable rise in the amino-acid concentration of the blood, nor was any increase of urinary nitrogen observed. In phloridzinized animals the injections caused no rise in the excretion of sugar. The oral administration of plasma protein, on the contrary, resulted in an increased urinary excretion of both nitrogen and sugar in phloridzinized animals. These observations suggest in explanation of their results that large aggregates of amino-acids (poly-

Thyroxine (p. 682), *3-5-diiodotyrosine* or *iodogorgoic ornithine* (p. 546) would have to be added in order to complete the list of known amino-acids.

THE ABSORPTION OF PROTEIN

isoelectric point—*isoelectric precipitation*.

According, however, to the *Zwiler hypothesis* the ampholyte molecule gives off, at the isoelectric point, *equal numbers* of basic and acid ions, thus leaving ions—the so-called *Zwitterions* (Ger. *Zwitter* = herma-phrodite)—holding equal numbers of negative and positive charges (formula II). Many proteins, e.g., metaproteins, casein, etc. are almost insoluble at the isoelectric point.

Under ordinary circumstances only negligible amounts of unchanged protein, or even such of its derivatives as proteoses, peptones and polypeptides, are absorbed into the blood from the alimentary tract. Generally speaking the protein molecule must first be hydrolyzed into its constituent amino acids. These are absorbed from the small intestine but not from the stomach. They enter the portal blood and, though to a very much less extent, into the lymph (chyle) and thence into thoracic duct.

Small amounts of certain proteins, e.g., raw egg white and blood serum are sometimes absorbed from the intestine into the blood stream. They are excreted in the urine to a large extent unchanged. Such absorption, which occurs more readily in young animals and children, should be regarded as a defect rather than as representing a physiological process. Nevertheless, experiments have shown that small quantities of protein introduced parenterally may be utilized by the tissues, and may even be capable of maintaining nitrogen equilibrium (p. 551). Though it is possible that the injected protein was broken down into its constituent amino-acids by the general tissue cells, it is more probable that this function was performed by the cells of the intestinal wall, and that the latter are necessary for the digestion even of protein introduced parenterally. It is, however, only for a short period and to a very limited extent that the body can utilize injected protein, for after a number of injections immunity is established to the foreign protein; an antibody known as a *precipitin* is formed which causes precipitation of the protein. Furthermore, if a subsequent injection is given two weeks or so after a single injection or after the last of a series of such injections, a most serious toxic state—*anaphylaxis*—may develop and prove fatal. In the human subject such anaphylactic (or anaphylactoid) reactions may follow the second injection of a foreign protein, e.g., diphtheria antitoxin (horse serum) or antitetanic serum. Skin rashes such as urticaria, erythema, eczema, giant edema, etc., or pain and swelling of the joints may occur. Collapse and death occasionally result (p. 263). The sensitivity of some persons to certain proteins is also sometimes responsible for dietary idiosyncrasies. Certain foods such as shell-fish, milk, strawberries, celery, etc., when ingested by persons sensitive to the

Classification of the amino-acids	
I. ALIPHATIC AMINO-ACIDS	
A. Monamino-monocarboxylic acids	
1) Glycine (or glycocoll) $C_2H_5NO_2$, or amino-acetic acid	$\begin{array}{c} \text{COOH} \\ \\ \text{CH}_2-\text{NH}_2 \end{array}$
2) <i>D</i> -Alanine $C_3H_7NO_2$ or α -amino-propionic acid	$\begin{array}{c} \text{COOH} \\ \\ \text{CH}_3-\text{CH}-\text{NH}_2 \end{array}$
3) <i>L</i> -Serine, $C_3H_7NO_2$, or β -hydroxy- α -amino-propionic acid	$\begin{array}{c} \text{OH} \quad \text{COOH} \\ \quad \\ \text{CH}_2-\text{CH}-\text{NH}_2 \end{array}$
4) <i>D</i> -Threonine $C_4H_9NO_2$, β -hydroxy- α -aminobutyric acid	$\begin{array}{c} \text{OH} \quad \text{COOH} \\ \quad \\ \text{CH}_2-\text{CH}-\text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
5) <i>D</i> -Valine $C_5H_{11}NO_2$ or α -amino-isovaleric acid	$\begin{array}{c} \text{CH}_3 \\ \\ \text{CH}-\text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
6) Norleucine $C_6H_{13}NO_2$ α -amino-caproic acid	$\begin{array}{c} \text{CH}_3 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
7) <i>L</i> -Leucine, $C_6H_{13}NO_2$, α -amino-isocaproic acid	$\begin{array}{c} \text{CH}_3 \quad \text{CH}_3 \cdot \text{CH}_2 \\ \diagdown \quad \diagup \\ \text{CH}-\text{CH}_2 \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
8) <i>D</i> -Isoleucine, $C_6H_{13}NO_2$, or β -methyl- β -ethyl- α -amino-propionic acid	$\begin{array}{c} \text{CH}_3 \cdot \text{CH}_2 \quad \text{COOH} \\ \diagdown \quad \\ \text{CH}-\text{CH}-\text{NH}_2 \\ \\ \text{CH}_3 \end{array}$
II. AROMATIC AMINO-ACIDS	
(16) <i>L</i> -Phenylalanine, $C_9H_{11}NO_2$, or β -phenyl- α -amino-propionic acid	$\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ \text{C}-\text{C} \\ // \quad \backslash \\ \text{C}-\text{CH}_2 \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
B. Monamino-dicarboxylic acids	
(9) <i>L</i> -Aspartic acid, $C_4H_7NO_4$, or amino-succinic acid	$\begin{array}{c} \text{COOH} \\ \\ \text{COOH} \cdot \text{CH}_2 \cdot \text{CH}-\text{NH}_2 \end{array}$
(10) <i>D</i> -Glutamic acid, $C_5H_9NO_4$, or α -amino-glutaric acid	$\begin{array}{c} \text{COOH} \\ \\ \text{COOH} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}-\text{NH}_2 \end{array}$
(11) <i>D</i> -Hydroxyglutamic acid, $C_5H_9NO_5$, or α -amino- β -hydroxy-glutaric acid	$\begin{array}{c} \text{COOH} \cdot \text{CH}_2 \cdot \text{CHOH} \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
C. Diamino-monocarboxylic acids	
(12) <i>D</i> -Arginine, $C_6H_{14}N_4O_2$, or δ -guanidin- α -amino-valeric acid	$\begin{array}{c} \text{NH}_2 \\ \\ \text{HN}=\text{C}-\text{NH} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
(13) <i>D</i> -Lysine, $C_6H_{14}N_2O_2$, or α - ϵ -diamino-caproic acid	$\begin{array}{c} \text{NH}_2 \\ \\ \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$
D. Sulphur containing amino-acids	
(14) <i>L</i> -Cystine, $C_6H_{12}N_2S_2O_4$, (or di-cysteine) or di- $(\beta$ -thio- α -amino-propionic acid)	$\begin{array}{c} \text{CH}_3-\text{S}-\text{S}-\text{CH}_3 \\ \quad \\ \text{CH}-\text{NH}_2 \quad \text{CH}-\text{NH}_2 \\ \quad \\ \text{COOH} \quad \text{COOH} \end{array}$
(15) <i>L</i> -Methionine, $C_5H_{11}SNO_2$, or α -amino- γ -methyl-thiol-n-butyric acid	$\begin{array}{c} \text{CH}_3 \cdot \text{S} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}-\text{NH}_2 \\ \\ \text{COOH} \end{array}$

CLASS OF PROTEIN	CHARACTERISTICS	EXAMPLES
C. Derivatives of proteins—derived proteins.—Continued		
(2) Metaproteins	Formed in a later stage of the action of acid or alkali	Acid metaprotein, alkali metaprotein
(3) Coagulated proteins	Formed by the action of heat or of alcohol upon solutions of proteins	Albumose from albumen, globulose from globulin, caseose from casein
(b) Secondary derivatives	Formed by the action of pepsin or trypsin upon proteins. They are soluble in water from which they are precipitated by saturation with ammonium sulphate. They are incoagulable by heat	
(c) Peptones	These represent a further stage in action of proteolytic enzymes. They are soluble in water but are not precipitated from an aqueous solution by ammonium sulphate. They are not coagulated by heat	
(d) Peptides, di-peptides, tripeptides and polypeptides	Products formed in the final stages of proteolytic digestion	Glycyl-alanine, leucyl-glutamic acid, etc.

amino-acid with the acid group of another and the liberation of a molecule of water. Thus

The junction, CO-NH, whereby amino-acids become grouped together is called the *peptide linkage*. The reverse process, namely, the separation of amino-acids from one another is also effected at this link in the chain, a molecule of water first being taken up. This process, which is called *hydrolysis*, may be illustrated thus.

Alanylglycine alanine glycine

Besides the simple chain-like combination of the amino-acids in the protein molecule a smaller proportion are believed to be united to form a series of closed-ring compounds—*diketopiperazines*. The ring structure is produced through the junction of free amino and carboxyl groups of amino-acids. Below is shown the production of diketopiperazine by the condensation of two molecules of glycine.

Protein, as a consequence of its constitution of amino-acids linked together as described above, con-

tains free NH₂ and COOH groups. By virtue of these it can act either as a weak acid or as a weak base; in acid solution it acts as a base yielding cations to form protein chloride, sulphate, etc. In alkaline solution it acts as an acid, yielding anions to form proteinates of sodium, potassium, etc. Substances which behave in this manner are termed *amphoteric*. Proteins are therefore amphoteric electrolytes or *ampholytes*. The extent to which a protein dissociates, i.e., yields anions or cations, depends upon the hydrogen ion concentration. At a certain critical hydrogen ion concentration which varies with different proteins, the protein molecule is electrically neutral. This is called the *isoelectric point*. The neutrality of the molecule at the critical hydrogen ion concentration has been supposed to be due to its dissociation being at a minimum, that is, to its giving off minimal numbers of either basic (+) or acid (−) ions (formula I below).

GENERAL DESCRIPTION AND CLASSIFICATION OF

PROTEINS

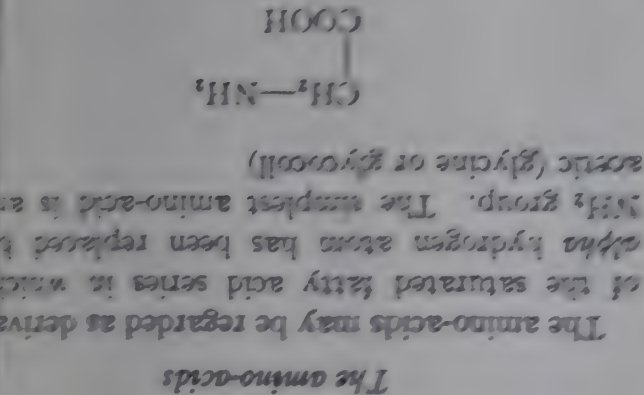

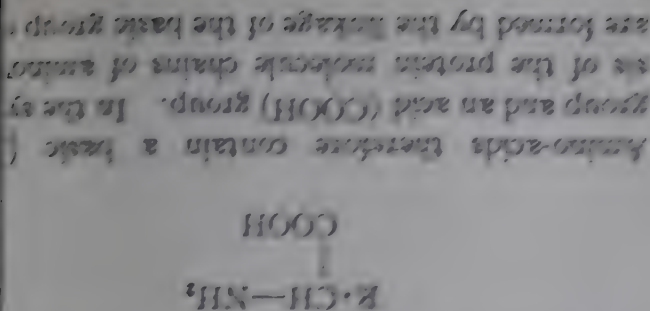

Protein is a basic constituent of protoplasm and consequently forms a proportion of all living tissues—animal or vegetable; of some tissues, e.g., muscle, it is the predominant solid constituent. It differs from the other foodstuffs—carbohydrates and fats—in containing (in addition to carbon, hydrogen and oxygen) nitrogen, sulphur and usually phosphorus. The molecules of certain proteins contain a prosthetic group, e.g., haemoglobin, glycogenase, leucine aminase, nucleoproteins, etc.

A classification and brief description of the various types of protein are given in table 46.

THE PROTEIN MOLECULE

The protein molecule is constructed of a number of units linked together. These units or "building stones" are called amino-acids. Some 23 different amino-acids have been identified as constituents of the protein molecule (see table 47). Some proteins contain nearly all of these in varying proportions; in others such as gelatin there are only 14 or 15 different kinds, some essential amino-acids being missing, while such simple proteins as the protamines, euryne and salmine, contain only 3 and 4, respectively. The single amino-acids have molecular weights ranging from 75 for glycine to over 200 for tyrosine and nearly 800 for threonine. The molecular weights of those proteins composed of large aggregations of amino-acids are correspondingly great and extend over a very wide range. The molecular weight of egg albumin, for example, is 35,000, that of haemocyanin, 5,000,000.

Protein molecules also vary in shape. Studies of protein structure by means of X-ray diffraction photography, reveal that the molecules of some proteins, such as keratin, collagen and myosin—the so-called fibrous proteins—have an elongated fibre-like form, resulting, it is believed, from the extended arrangement of the polypeptide layers of which the molecule is constructed (see below). When reversed with molecules assume elongated and further on return to their previous lengths when released from the stretching force. The

changes in length are described as being folding and unfolding of the polypeptide chain in a concertina-like fashion. Other proteins are folded or arranged into a lattice pattern form a compact structure of a more or less globular shape. Unfolding and the assumption of a permanent extended form is associated with denaturation. Proteins of approximately the same molecular weight may differ considerably in molecular structure and for this reason may differ in such physical properties as elasticity, osmotic pressure or viscosity. The fundamental structure of all proteins is believed by Astbury to be fibrous, but the intermolecular arrangement of the polypeptide chains varies widely between different types and in the same protein under different conditions. Thus a variety of patterns produced.

The average elementary composition of a molecule of a protein such as albumin or globulin is as follows: C, 54 per cent; H, 7 per cent; N, 16 per cent; S, 1 per cent; O, 22 per cent.

The amino-acids

The amino-acids may be regarded as derivatives of the saturated fatty acid series in which the α hydrogen atom has been replaced by an NH_2 group. The simplest amino-acid is aspartic (glycine or glycocoll):

that the metabolism of the new-born infant and the post-partum metabolism of the mother added together practically equalled the metabolism of the pregnant state near the end of term. Boothby and Sandiford estimated the surface area of the fetus throughout gestation and concluded that the excess heat production of the pregnant state was derived from the fetus and the increased mass of the maternal structures, the energy

(2) RACE AND CLIMATE. Some oriental races show a slightly lower rate (from 10 to 15 per cent)

The metabolism of the new-born is much lower than that of infants a few weeks older. Premature infants have a lower rate than those born at full term. Females have a metabolic rate a little lower than that of males in the same age group. The relationship of heat production to age and sex is given in table 44.

Man occidentals living under the same climatic conditions; others show little difference. In one oriental race (the Miao of West China) and in the Maya of Central America and the Mapuches of Chile the basal metabolic rate is actually higher than that of whites. The rate is also higher in Eskimos. The basal metabolism of white persons in a tropical climate is usually reduced. (3) HABITS. Owing to the greater development of their muscular tissues and athletes and laborers have in general a higher B.M.R. than persons leading a sedentary life. (4) PREGNANCY. The basal metabolic rate of the pregnant woman shows little change until the sixth or seventh month when the fetus causes an appreciable increase in the weight of the mother. The metabolism of the mother from this time to term is the sum of her own metabolism in the non-pregnant state and that of the fetus. It is found by Murlin and Carpenter, for example,

production per unit of mass of the maternal organism remaining constant. Normal preg-

The latter are derived from the break-down of nuclear material as well as from free mononucleotides, e.g., adenylic, inosinic and guanylic acids, found in muscle and glandular structures. Muscle and more especially glandular tissues, e.g., thymus, liver, kidney, pancreas, testes, etc., and leguminous vegetables are food rich in purines.

Uric acid is formed from urea in the liver of the bird, but the site of its formation in the mammal is unknown. We have already seen that in the dog uric acid accumulates in the blood after removal of the liver. On the other hand, in man, the liver is the only tissue, according to Jones, which contains xanthine oxidase, which suggests the possibility that uric acid production in the human subject is essentially a hepatic function. The results of the investigations of Folin and associates indicate that from 30 to 70 per cent of the uric acid produced by the human subject is destroyed, the remainder appearing in the urine. The liver is probably the site of uric acid destruction. Little information is available concerning the process, and its end products are unknown; allantoin is not one of them however, since human urine contains insignificant amounts of this substance, and what little is present is simply that taken preformed in the food. Uric acid is excreted in the urine as the urates of sodium, potassium and ammonium, and in the free state. After urine has been voided a crystalline deposit of urates and free uric acid appears. The average daily output of uric acid is from 0.5 to 1 gram. Of this the endogenous uric acid amounts to from 0.3 to 0.4 gram. Muscular tissue most probably furnishes the precursors of endogenous uric acid, exercise causing a rise in the uric acid of the blood, and increased excretion in the urine.

Protein (purine-free, e.g., milk, eggs) and carbohydrate foods accelerate the excretion of uric acid, and lower its level in the blood.⁵ Food fat has the reverse effect—reduced excretion and a raised level in the blood.

Small quantities (15–45 mg. daily) of purines are excreted in the urine. These include adenine (but not guanine), hypoxanthine and xanthine, as well as the methyl purines contained in beverages. The latter are caffeine (1-3-7 tri-methyl-xanthine) of coffee, *theophylline* (1-3-di-methyl-xanthine) of tea and *theobromine* (3-7 di-methyl-xanthine) of cocoa. The methyl purines

⁵ The possibility has been suggested in the past that a proportion of the uric acid formed in the human body is derived, as the great part of it is in birds, from the catabolism of protein. There is no reason to believe, however, that a conversion of this nature occurs to any significant extent.

undergo partial demethylation in the body and are excreted as mono- and di-methyl purines. It appears that theobromine is excreted entirely in this form and is not converted to uric acid. Caffeine and theophylline on the other hand are converted in considerable amounts to uric acid and excreted as such. This is an important point to bear in mind when considering dietary restrictions for gouty subjects.

GOUT

Normal blood contains, on the average, about 3 mg. (2.5 to 5.0 mg.) of uric acid per 100 cc. In gout the concentration of uric acid in blood is raised and may be as high as 10 mg. per cent while its excretion in the urine is reduced. The excretion of uric acid after a meal rich in nucleoprotein, as well as the endogenous uric acid excretion, that is, the excretion on a protein-free diet, are much less in the gouty than in the normal subject. The diminished excretion of uric acid is particularly well marked just prior to an acute attack of gout. There may be no rise, however, in the blood uric acid at this time. A characteristic feature of gout is the formation of deposits of the sodium salt of uric acid (sodium urate) in the form of crystals in the cartilaginous tissues. The deposits or *tophi*, as they are called, occur most commonly about the joints of the great toes and fingers. During the gouty attack the joint becomes acutely inflamed and tender. The etiology of gout is obscure. One type of the disease occurs in association with chronic lead poisoning.

There is no reason to believe that the *hyperuricemia* of gout is the result of an increased production of uric acid in the body, nor is it due, apparently, to diminished destruction of uric acid. It is quite evidently due to reduced excretion. Nevertheless, the uric acid retention is not due to renal failure in the ordinary sense of the term, and though gout and kidney disease are not infrequently associated, the high concentration of uric acid in the blood of the gouty subjects is the forerunner of the kidney damage, rather than that the latter is the primary cause of uric acid retention. Furthermore, a level of uric acid may be present as in nephritis and other conditions without any sign of gout. These facts make it difficult to find a satisfactory explanation for the high uric acid level in the blood in gout. Minkowski suggested that normally uric acid existed in blood in combination with a nucleoside which was decomposed by the kidney cells, the uric acid being excreted. In gout, it was supposed, this specific renal function was impaired. Benedict and his colleagues have obtained evidence in favor of such a view. They claim to have demonstrated the presence of two forms of uric acid in the blood of the ox and other animals, and in man. Freshly drawn ox blood contains 0.5 mg. per cent of uric

acid. Ten times this amount was obtained when the blood had been allowed to stand, or had been boiled with hydrochloric acid. This suggested that the uric acid was present largely in some stable, combined form which was decomposed by the action of an enzyme or by treatment with acid. The combined form is present exclusively in the erythrocytes. It is made up of a molecule each of uric acid and a pentose—d-ribose.

The formation of tophi is not simply the result of the saturation of the blood with uric acid. The concentration of uric acid never reaches the limit of its solubility in blood. In other conditions, e.g., nephritis and leukemia, associated with a high blood uric acid, deposits do not occur: some local factor apparently is necessary for deposition to occur. The process is possibly in the nature of vicarious excretion of uric acid into certain tissues (Benedict) wherein, the uric acid upon reaching the saturation point, is deposited as crystals of sodium urate.

The treatment of gout is directed toward the reduction of the purine intake. We have seen that carbohydrates and purine-free proteins increase uric acid excretion at the same time lowering the blood level, and that fats have the opposite effect. The diet should be planned with these facts in mind. Salicylates, aspirin, cinchophen (atophan) which are used in the treatment of gout

have been shown to increase uric acid excretion and to lower the level of blood uric acid. Alcohol appears to exert little effect upon the latter though it is usually banned from the diet. Coffee and tea since their methyl purines are partly excreted as uric acid are restricted.

Other conditions associated with a high level blood uric acid are:

(a) *Leukemia and polycythemia.* The elevation of the blood uric acid in these conditions is usually associated with symptoms of gout. The high level of blood uric acid is evidently due to increased production and not to failure in excretion. In leukemia, for example, the amount passed daily in the urine may be as much as 12 grams. The increased uric acid production in this condition is probably due to the disintegration of body tissue, generally rather than, as has been supposed, to the destruction of white cells. (b) *Pneumonia.* (c) *Nephritis.* In renal failure the uric acid is one of the first of the nitrogenous substances of the blood to show a rise. (d) *Lead poisoning.* (e) *Toxemias of pregnancy.* (f) In certain other conditions associated with a high non-protein nitrogen of the blood.

CHAPTER L

CARBOHYDRATE METABOLISM

Since all carbohydrates are soluble in water these constituents accumulate in the extract when a tissue is thoroughly extracted with this solvent. Hot water is more effective than cold in extraction and has the further advantage that enzymic actions are inhibited. Thus the carbohydrate substances in the extract are more nearly in the form in which they occur in the living tissues.

Without doubt the carbohydrate substance most important in metabolism is glucose. All organisms appear to be able to utilize glucose. Glucose, sometimes called dextrose because its solution rotates the plane of polarized light in a dextro-rotatory direction and often written d-glucose, dissolves in water to give an equilibrium mixture of α and β -glucose, approximately two-thirds of the glucose being of the α form. The formulae of these two isomers are written.

It will be noted that a cyclic structure has been accorded the glucose molecule.¹ In this case the ring is composed of five carbon atoms and one

¹To account for the characteristic reducing properties of glucose it is presumed that in solution there

exists a very small amount of the open chain aldehydic form in equilibrium with the cyclic forms.

oxygen atom, sometimes referred to as an amylenic oxidic ring. α and β isomers of glucose may also possess a ring composed of four carbon atoms and one oxygen atom. This is the so-called γ -glucose. Such a ring is a butylene oxidic ring. These forms of glucose are very reactive, that is, unstable. They have not been isolated. It may be pointed out, as an example of their reactivity, that they reduce Fehling's solution in the cold. Because of this marked reactivity it has been postulated that such compounds must be the first intermediaries in glucose metabolism. But there is no conclusive evidence for such a change, and all theories of glucose metabolism involving the formation of a "reactive" form of glucose have very little factual basis. Glycogen, or animal starch, is a polysaccharide composed of glucose units and so is written $(\text{C}_6\text{H}_{10}\text{O}_5)_x$ [according to Haworth, $x = 12$. In liver glycogen formed from galactose x may equal 18 (Bell)]. Glycogen is widely distributed in the animal body, but the bulk occurs in the muscles and the liver. Glycogen may be isolated from tissue by hot water extraction, or more readily and completely by hot alkali. It is worthy of note that whereas polysaccharides are very stable in alkaline solution, monosaccharides (glucose, fructose, galactose, etc.) are unstable. The reverse behavior is exhibited in acid solution.

Glucose occurs in the body in combination with other substances. Thus as salts of glucose phosphoric acids, and in the lactating animal in combination with galactose as lactose, which is α - and β -glucose β -galactoside.

Galactose (open chain form)

exists a very small amount of the open chain aldehydic form in equilibrium with the cyclic forms.

The slight difference in chemical configuration between glucose and galactose should be noted. Carbohydrates occur as substituent groupings in certain proteins. Such proteins may be extracted from tissues paying due regard to their solubility properties. From such extracted proteins there has been isolated glucose (from glycoproteins) glucosamine, mannose (from certain blood proteins) and various pentoses that is 5 carbon sugars possessing the general formula ($\text{C}_5\text{H}_{10}\text{O}_5$) in nucleic acid which is combined with certain proteins to give the so-called nucleoproteins (p. 564). It may be pointed out that pentoses also occur in combined form as nucleotides, and that very rarely cases of human pentosuria are encountered.

Carbohydrates also occur linked with fatty substances. Thus the cerebrosides contain within their molecule galactose units. The galactose is present in the normal or amylenic oxidic ring form. Cerebrosides may be extracted with the usual fat solvents. The galactose may be split off from such extracted substances by acid hydrolysis. Glucose may also be present in cerebrosides (p. 597).

METHODS OF ESTIMATION:

Glucose. The simple sugars have three properties which permit their identification and estimation (1) their ability to reduce the salts of heavy metals in alkaline solution (2) their optical activity (3) fermentation by yeast and by various microorganisms. The methods depending on the reduction of the salts of heavy metals have been of great value in physiological work but since other compounds present in the body also possess this property it is necessary to prove that the reduction is due to glucose. This is accomplished by utilizing the third property mentioned above, i.e.,

by fermenting the glucose with yeast or with certain microorganisms. The optical activity of the carbohydrates is an invaluable property when they are present in solutions uncontaminated by various other optically active substances which are present in physiological fluids.

Glycogen. Glycogen is very resistant to alkaline hydrolysis, but, as Claude Bernard discovered, readily yields reducing sugar on acid hydrolysis. Pflüger boiled glycogen for several weeks in strong alkali without destroying it. Advantage is taken of this property to free glycogen of contaminating substances. After alkaline hydrolysis of the tissue the glycogen is precipitated from solution by alcohol. This material is then broken down by acid hydrolysis to glucose, which is stable in acid solution. The sugar is then estimated as described above and the amount of glycogen calculated from the result. There is no accurate method of estimating glycogen as such.

Lactic acid. In muscle, glycogen is broken down to lactic acid during muscular exercise and in the recovery from exercise part of it is resynthesized to glycogen. The lactic acid is estimated by oxidation to acetaldehyde and the latter is determined by distilling it into sodium bisulphite with which it forms a double compound. Residual unbound bisulphite is titrated with iodine.

APPROXIMATE DISTRIBUTION OF CARBOHYDRATES:

	Liver per cent	Muscle per cent	Blood per cent
Glucose.....	0.06- 0.15	0.02-0.04	0.08-0.11
Glycogen.....	0.2 -10.0	0.2 -1.8	trace
Lactic acid...	0.01	0.01	0.01

Liver is 3.3 per cent, muscle 50 per cent and blood 8 per cent of body weight. Glucose and lactic acid are found in the other soft tissues and some of these contain small amounts of glycogen. The glycogen content of kidney and of heart muscle has been extensively studied under various physiological and pathological conditions.

ABSORPTION OF SUGAR

The monosaccharides formed during digestion are rapidly absorbed from the small intestine. In the rat, galactose disappears from the intestine most rapidly, glucose a little more slowly and fructose much more so. There is, therefore, a selective action of the intestinal cells in the absorption of sugars (Cori). Evidence is accumulating that the absorption of sugar may proceed against a concentration gradient i.e. when the concentration is lower in the lumen of the small intestine than in the blood. There is an increase in the amount of esterified phosphate in the intestinal mucosa dur-

ing the absorption of both glucose and fructose but this phosphorylation may be related to metabolism rather than to absorption. It has, however, been suggested by Lundsgaard that the relatively high level of esterified phosphate in the intestinal mucosa during the absorption of fructose may be due to slow dephosphorylation and thus account for the well known delay in the rate of absorption of this sugar.

The slow absorption of glucose from the small intestine after hypophysectomy or adrenalectomy may be a part of the picture of inanition rather than a result of the loss of a specific adrenal phosphorylating factor, as has been suggested. The fact that the administration of sodium salts restores the rate of glucose absorption in adrenalectomized animals (Deuel) is in favor of the non-specific effect.

Glucose is not absorbed in appreciable amounts from the stomach until high concentrations are reached, and only slowly from the large bowel.

THE FATE OF INGESTED OR INJECTED GLUCOSE

There is good evidence that no other monosaccharide is as effective in the liverless animal as glucose. This finding suggests, and there is indeed good evidence, that the other monosaccharides are normally changed to glucose in the liver. Fructose is a better glycogen former than glucose but galactose is much inferior in this respect. When glucose is absorbed or is injected some of it can be accounted for by the increase in liver glycogen, some is converted to muscle glycogen and some is oxidized. The concentration of glucose in the soft tissues is temporarily raised.

THE FORMATION OF GLUCOSE IN THE BODY

Glucose is apparently formed in appreciable amounts only in the liver. When this organ is removed (Mann and Magath) hypoglycemia soon appears and sugar must be provided if the animal is to survive more than a few hours. Sugar is made from protein in the liver and evidence obtained on phloridzinized animals indicates that some of the amino-acids, glycine, alanine, cystine, aspartic and glutamic acids may yield glucose in the theoretical amounts (Lusk). It is well established that plants form sugar from fat and this possibility must be considered in animals. Direct evidence for this conversion is not available in animals. There are a certain number of reports of respiratory quotients below 0.7 which disturb those who believe in the unitarian significance of the quotient, but this ratio should not be used as a weapon against itself. If sugar formation from fat does take place, all the evidence suggests that the liver is the principal site of the change.

A discussion of the indirect evidence in favor and against the conversion of fat to sugar will not be attempted here. See Lusk "The Science of Nutrition", Macleod "The Fuel of life", and the more recent reviews by Soskin, who summarizes evidence in favor, and by Stadie, who believes this change does not take place in animals.

FORMATION AND BREAKDOWN OF GLYCOGEN AND THE OXIDATION OF SUGAR

Great advances in our knowledge of the most fundamental aspects of carbohydrate metabolism have been made in recent years. Most of the steps in the formation and breakdown of glycogen

Formation and Breakdown of Glycogen and Oxidation of Carbohydrate

and the oxidation of sugar have been revealed by the work of Harden, Young, Embden, Meyerhof, Warburg, Cori, Lohmann, Peters and numerous other investigators. Many of the individual steps are not observed in the intact cell since the intermediate products which have been identified "in vitro" do not accumulate. There are, for example, some twelve enzymatic reactions involved in the anaerobic conversions of glycogen to lactic acid. Practically all of these have been shown to be reversible but since the final product of one reaction is immediately removed by the following step the process proceeds in one direction. The phosphorylation of glycogen and of glucose has been proved to be the introduction to a long series of changes by which these products are transformed through various phosphate esters to pyruvic or lactic acid. Glycogen after phosphorylation breaks down to glucose-1-phosphate. This (Cori ester) is converted to glucose-6-phosphate which is also the first step in the oxidation of glucose.

The work of Cori and Cori in which the enzyme phosphorylase, which catalyses the reversible reaction glycogen (or starch) + inorganic phosphate \rightleftharpoons glucose-1-phosphate, was isolated and purified is of great interest. This enzyme is widely distributed in animal tissues and is responsible for the first stage in the breakdown of glycogen. It also affects the synthesis of a polysaccharide indistinguishable from glycogen. Some glycogen must be present to "prime" this latter reaction and adenylic acid is an essential constituent of the mixture for activity in either direction. It is of significance that one of the fundamental reactions of carbohydrate in the animal body glycogen \rightleftharpoons glucose can be demonstrated in the test tube in the absence of any of the hormones which affect the rate of this reversible change under physiological conditions.

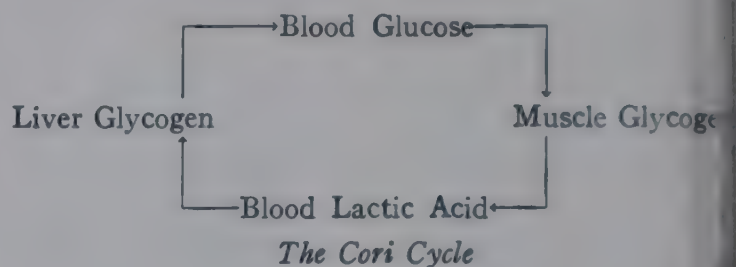

It may be emphasized again here that the intermediate steps between glycogen and glucose are phosphorylated compounds.

It is now well established that this transfer of phosphate groups is of paramount importance in the mechanism by which cells derive energy from the breakdown of food materials. Muscle glycogen breaks down to CO_2 and H_2O under physiological conditions. The steps from glycogen to pyruvic acid can occur anaerobically but from pyruvic acid on, an adequate oxygen supply is necessary. When there is a relative lack of oxygen

lactic acid is formed. This lactic acid may diffuse out into the blood stream and it is then converted in the liver to glycogen.

This part of the so-called Cori cycle is apparent not brought into play under ordinary circumstances but is involved in muscular exercise and under conditions of anoxia.

Glycogen-containing tissues, with the exception of the liver, exhibit the same pattern of breakdown of this polysaccharide as has been described in muscle. In the liver, glycogen does not normally break down to CO_2 and H_2O or to lactic acid but to dextrose. This is probably due to the fact that the liver contains a very active phosphatase which converts the glucose-1-phosphate and the glucose-6-phosphate to glucose and thus removes these esters from the medium.

Under certain conditions, *in vitro*, glyceric aldehyde phosphate and dihydroxyacetone phosphate can be isolated from the breakdown products of muscle glycogen. In the diabetic dog these substances, and also pyruvic acid, form "extra sugar" but so does methyl glyoxal which is not a part of the accepted schemes. In the living organism it is impossible to decide at present whether these substances, when administered, are used instead of glucose or are actually converted to glycogen or glucose before utilization. The use of appropriate tracer substances may help to solve these problems.

THE REGULATION OF BLOOD SUGAR

The blood sugar level represents the resultant of oxidation, storage and excretion on the one hand and formation and absorption on the other. This may be represented graphically.

The relative constancy of the blood sugar which is an equilibrium mixture of α and β glucose in the normal fasting animal is made more remarkable by the fact that the production, storage, and utilization of sugar are affected by a great number of chemical and nervous factors.

When sugar is not being absorbed from the intestinal tract it must be made in the liver from non-carbohydrate sources or liberated by the breakdown of liver glycogen. The liver glycogen is the emergency supply which is available while

the process of gluconeogenesis is gathering speed. In the average man approximately 100 gms. of glycogen are present in the liver and this would only supply the demands for sugar for some five hours if the gluconeogenesis were to cease. The rate of glycogen breakdown is affected by adrenaline which is liberated in emergencies, and the rate of gluconeogenesis by the internal secretions of the anterior pituitary gland, the adrenal cortex, the thyroid and the pancreas, as will be discussed later. An important part of this homeostatic mechanism for the regulation of blood sugar appears to be the level of blood sugar itself (Soskin). Under experimental conditions in which variation in the rate of secretion of insulin is impossible, i.e. in the depancreatized dog given insulin at a constant rate, indirect evidence indicates that the administration of dextrose decreases the rate of output of sugar

production in an excessive rate of discharge of sugar from the liver. Disturbances in endocrine function are the main causes and the mechanism of these changes will be discussed later.

Transient hyperglycemia may be due to either physiological or pathological processes. Alimentary hyperglycemia is a physiological process and its height depends on the amount and nature of the carbohydrate in the meal. Adrenaline hyperglycemia is a part of the physiological response to an emergency. Nerve impulses acting on the liver, changes in hydrogen-ion concentration of liver cells due to asphyxia or other causes, may produce a transient rise in blood sugar. Toxic products of infection acting on the liver to increase gluconeogenesis or on tissues in general to diminish utilization of sugar may produce a hyperglycemia of short or long duration.

by the liver. In the intact animal the pancreatic mechanism is also involved. The insulin content of the blood probably determines at what level of blood sugar gluconeogenesis in the liver will be inhibited. In the absence of insulin there is no evidence that any level of blood sugar inhibits the new formation of sugar.

HYPERGLYCEMIA

An increase in the blood sugar beyond the normal range constitutes a hyperglycemia. This is a protective phenomenon. With the exception of insulin a rise in blood sugar provides the greatest single stimulus for the formation of glycogen and the utilization of glucose.

Prolonged hyperglycemia may be present when either or both of the following processes are operating (1) diminished utilization of glucose, (2) over-

PANCREATIC DIABETES

Removal of the pancreas

When the pancreas is completely removed from a dog or cat, a characteristic syndrome rapidly develops (Mering and Minkowski, 1889). When a diet including the known essentials is provided, the animals may live indefinitely if adequate amounts of insulin are administered. The animals recover rapidly from the operation and appear normal, but the diabetic state quickly supervenes when insulin is discontinued. The sugar content of the blood begins to rise within a very short time, depending on the size of the last dose of insulin, and increases from the normal level of 0.08–0.11 per cent to 0.20–0.40 or higher within twenty-four hours. The urine gives a positive Benedict's qualitative test for sugar when the

blood sugar rises above approximately 0.16 per cent. This point, the so-called renal threshold, is the level of blood sugar above which large amounts of sugar are excreted in the urine. In some animals the "threshold" rises when the diabetic state is allowed to persist. (There is some glucose in normal urine and small amounts of other sugars.) The excretion of nitrogen is increased and this may be taken to indicate protein breakdown. The ratio of glucose to nitrogen excreted in phloridzin poisoning is 3.6:1 but this ratio is not observed in depancreatized dogs and indeed that obtained is so variable that little significance can be attached to it. The ratio is low in animals on a high protein diet and there is evidence that the addition of fat may increase it somewhat. It is established that glycerol may be converted to sugar. In the fasting diabetic the blood sugar and sugar excretion are maintained at high levels. The sugar is apparently formed from body protein in the liver since the blood sugar of the diabetic falls rapidly after hepatectomy. The loss of protein contributes to the decrease in body weight.

The disturbed metabolism of fat in the depancreatized animal is indicated by the accumulation of the ketone bodies in the blood and by the excretion of excessive amounts in the urine. The ketosis in a fat dog is greater than in a lean, but this species is characterized by its efficiency in metabolizing fats, without ketosis. The loss of body fat is rapid but the ketosis may be so severe, even in this species, that the animal dies in coma before the fat reserves are depleted.

β -hydroxy-butyric and aceto-acetic acids and others derived from tissue breakdown appropriate base and thus when the available reserve of base is depleted may produce an acidosis. In acidosis the respiratory center is stimulated and "air hunger" and coma are produced. The exact mechanism of coma production in diabetes is not known. Some observers believe that aceto-acetic acid is particularly toxic. This acid is oxidized in the bladder and lungs to form acetone, which is excreted in the urine and expired air.

The neutral fat content of the blood increases due probably to the increased rate of mobilization of depot fat and there is also a rise in cholesterol esters and the phospholipid.

Very few authorities will deny that the evidence for the increased rate of production of sugar from protein in pancreatic diabetes is satisfactory. While there is an abundance of evidence that the depancreatized dog can still burn sugar—all the

criteria of sugar combustion in the normal have been satisfied—it is not permissible to conclude that there is not some interference with the process. The rapid sugar utilization in the hepatectomized diabetic animal and the production of the diabetic condition by the administration of the diabetogenic substance of the anterior pituitary which apparently acts, in part, by stimulating the liver to produce more glucose, tend, however, to emphasize over-production rather than under-utilization. On the other hand the anterior pituitary contains substances which inhibit the utilization of glucose.

The respiratory quotient of the depancreatized animal not receiving insulin assumes the low level 0.69–0.73 and is not usually raised when sugar is given. Under certain conditions, in animals which have received a high protein diet and insulin, for a time the quotient may be higher (Soskin). The characteristic low quotient may indicate combustion of fat but if any process, such as conversion of fat to sugar which gives a very low quotient, should be taking place the ratio might indicate the resultant between sugar combustion, fat combustion, and the conversion. In brief, since more than one interpretation of a quotient is possible great caution must be observed in drawing conclusions with regard to its significance. When the liver is removed from a depancreatized dog the quotient rises, indicating either that relatively more sugar is being burned or that conversions giving a low quotient are taking place to a smaller extent.

The glycogen content of the muscles of a depancreatized animal may be reduced below the normal level, but appreciable amounts remain. There is no diminution of heart muscle glycogen and recently convincing evidence of an increase has been obtained. Liver glycogen falls to very low levels. A slight increase in both muscle and liver glycogen can be produced by giving large amounts of sugar without insulin.

While the glucose utilization of the normal heart is low, that of the diabetic animal is even less when the blood sugar concentrations are the same. Lactate, however, is used almost as well by the diabetic as by the normal heart (Lovatt Evans). These findings eliminate the necessity of supposing that the diabetic heart depends for its energy entirely on protein and fat. The rate of usage of glucose but not of lactate by the diabetic heart is increased when insulin is supplied (see also p. 267).

The excretion of phosphorus is increased in the depancreatized animal. The administration of

sugar or adrenaline does not cause the prompt fall in the inorganic phosphate of the blood which is observed in normal animals. These substances, therefore, produce their effects by raising blood sugar which in turn calls forth insulin, or reduces the rate of sugar production by the liver. Adrenaline and insulin thus affect blood inorganic phosphate similarly.

The diabetic animal is very susceptible to infections but it is not established that this is due to the raised sugar content of the tissues. The specific antibodies are not significantly altered in amount but other defence mechanisms may be made less effective by the abnormal metabolic condition

and exhibit only a mild form of diabetes. Severe diabetes produced under these conditions by administration of the diabetogenic substance of the anterior pituitary is alleviated by insulin.

THE ANTIDIABETIC HORMONE—INSULIN

The name *insuline* was suggested by de Meyer in 1909 for the hypothetical internal secretion of the pancreas the search for which had been stimulated by von Mering's and Minkowski's findings (1889). While other workers, among whom Hédon, Zuelzer, and Scott may be mentioned, obtained very suggestive results, which in some cases were probably due to the presence of insulin, Banting

FIG. 232. Effect of insulin on the blood sugar curve of a depancreatized dog (redrawn from Banting and Best). (1) Injection of extract of degenerated pancreas; (2) extract after incubation with pancreatic juice; (3) extract incubated without pancreatic juice. Blood sugars by Myers-Bailey modification of Lewis-Benedict method.

which exists. Pathological conditions are observed with considerable frequency in the eyes of diabetic animals. The liver rapidly undergoes extensive fatty degeneration and there may be an accumulation of large amounts of neutral fat (p. 1012).

While there is considerable variation in the length of life of the depancreatized dog or cat, most individuals fed on a mixed diet do not live for more than two or three weeks without insulin. Under certain conditions dogs may survive for seven weeks. It is now established, however, that when the anterior pituitary is also removed the animal (dog) may live for nine months, at least,

and Best working in Macleod's laboratory (1922) were the first to obtain a preparation containing the antidiabetic hormone in a form which consistently alleviated all signs of diabetes in completely depancreatized dogs (fig. 232).

SOURCE OF INSULIN

While it is reasonable to suppose that small amounts of insulin are present in tissues other than the pancreas, methods are not yet available for their estimation. Blood provides an exception to this generalization but the active substance is detected by the intravenous administration of the whole blood and not by extraction of the insulin

from the tissue. A reliable procedure for the determination of insulin in blood would unquestionably result in great advances in our knowledge of carbohydrate metabolism. Gellhorn and his associates, among others, have recently suggested

the only organ to manufacture insulin or to store it in more than minute amounts.

The islet cells of the pancreas are of four types— α , β , γ and δ . The α and β types contain granules. The γ are non-granular. The δ cells have

(b)
FIG. 253

methods based on the susceptibility to insulin of small animals from which the adrenal medulla and pituitary glands have been removed. Much further work is required in this field. In the mammalian organism the pancreas appears to be

been seen only in human pancreas (Bloom) and are not well defined. In dog pancreas the number of cells per islet varies greatly, as do the relative numbers of the various types of cells. One study gives the average number per islet as 30 and the

verage ratio of α to β cells as 20:75. The islet volume may be about one one-hundredth of the pancreas. The β cells occupy the periphery of the islets and are smaller than the others. It is these β cells which are considered to be producers of the antidiabetic hormone; indeed, the granules of these cells may consist largely of this substance. Epithelial cells of the small ducts are considered to be the "mother cells" of the islet and acinar cells. New islet cells may, therefore, be produced from them.

The main points of evidence which indicate that the hormone is produced in the islet cells are as follows: 1. Histologically, the islets are glandular structures, the obvious outlet for the secretion of which is through the blood stream. 2. There are relatively large amounts of the hormone in the principal islets of teleosteal fishes, in which few enzyme-producing cells are found. 3. The active substance is found in degenerated pancreas in which the loss of acinous tissue has proceeded more rapidly than that of the islet cells. Ligation of the pancreatic ducts eventually produces a decrease in the insulin content of the pancreas, but moderate amounts of insulin may still be extracted when very few enzyme-producing cells remain. 4. When most of the pancreas, approximately nine-tenths, is removed from a dog, characteristic lesions (hydropic degeneration) are found in the β cells of the remnant. These changes can be accelerated by a high carbohydrate diet, and prevented or eliminated by administration of insulin or by fasting. 5. The clinical condition known as hyperinsulinism occurs when the pancreas liberates abnormally large amounts of antidiabetic hormone. In many of the cases there are definite tumors of the islet cells. After operative removal of these masses of islet cells the blood sugar is maintained at higher levels. 6. Metastases in other tissues arising from carcinoma of the islet cells have been shown to contain insulin. 7. The injection of anterior pituitary extracts leads to destructive changes in the islet cells, chiefly in the β cells, while there is little or no effect on the α cells. The pancreases from a number of dogs treated with these extracts have been assayed for their insulin content, and the values obtained were roughly proportional to the concentration of granules in the β cells as determined by histological studies of these tissues, using Bowie's staining technique.

CHEMISTRY OF INSULIN

Insulin was first obtained in crystalline form by J. J. Abel and his colleagues in 1926. In 1934

D. A. Scott showed that the crystalline material was the salt of insulin with a metal such as zinc, cobalt, cadmium or nickel. The active material is a protein. It may be regarded as an albumin. By the Svedberg ultracentrifuge method it has a molecular weight similar to that of egg albumin, namely, 35,000. It now can be readily crystallized, usually in the form of twin rhombohedra of microscopic size, at a hydrogen-ion concentration

(Kindness of Dr. D. A. Scott)

FIG. 234

a little above its isoelectric point (pH 5.2), provided salts of zinc, nickel, cadmium or cobalt are present in the solution. These metals are evidently linked chemically with the protein in its crystalline state, for they occur in constant amounts and these amounts are proportional to their atomic weights. Zinc is present in zinc insulin crystals to the extent of nearly 0.5 per cent. The fact that normal pancreatic tissue is relatively

rich in zinc may be of some significance in the storage of the hormone in the gland. The protein has a high sulfur content (3.2 per cent), all present in the form of cystine. The molecule contains no carbohydrate material, and apart from its low mineral content, appears to be wholly constituted of amino acids. The constituent amino acids and their percentage distribution are as follows: serine 3.6, threonine 2.7, glutamic acid 21, cystine 12.9, leucine 30, lysine 1.3, arginine 3.3, histidine 4, phenylalanine 8.4, tyrosine 12.8, proline 10.

Slightly acidified insulin has been kept for long periods, but in dilute alkali insulin is relatively unstable. It is hydrolyzed and so is rendered physiologically inactive by those enzymic preparations which attack proteins. Thus, trypsinogen is without effect on insulin, and a portion of pancreas may be incubated at 37 C. for some hours without any alteration in the amount of insulin which can be extracted from it. Various attempts have been made to ascertain if there is in the molecule a specific grouping of certain of the amino acids which is really responsible for its hormonal activity. It may be concluded that the physiological activity of insulin may be slightly and sometimes reversibly decreased by certain minor chemical changes in the molecule, whereas appreciable chemical alteration gives a considerable diminution or complete absence of activity. These considerations are linked with the fate of insulin in the animal body after secretion from the pancreas or after parenteral injection. Proteases of the blood and other tissues may effect considerable destruction. Other changes have been suggested, such as the action of sulfhydryl groupings, as in glutathione, which may reduce the cystine disulfide linkage, a change which is known to be accompanied by inactivation.

STANDARDIZATION

Zinc insulin crystals from all sources so far examined (man, cattle, hog, sheep, bison, fish) have the same potency. Very recently, preparations of zinc insulin crystals have been made of slightly greater potency than usual. This work may have considerable theoretical interest. The international standard, a preparation of zinc insulin crystals, is defined as containing 22 units per milligram. There are two well established methods of assaying the potency of an insulin preparation. The lowering of blood sugar in fasting rabbits and the production of convulsions in fasting mice both furnish satisfactory effects of insulin for the comparison of unknown and standard products.

LIBERATION OF INSULIN

The arrangement of the capillary loops about the islet cells and the reported scarcity of lymph channels provide morphological evidence in favor of the capillary blood stream as the pathway by which insulin reaches the systemic circulation. It is important to remember that insulin passes first to the liver.

While there are many pieces of experimental evidence which support the conclusion that the level of blood sugar is an important factor in the regulation of insulin liberation, the possibility that a decrease in the rate of discharge of sugar from the liver may also be produced when the blood sugar is raised, is frequently overlooked.² This latter effect is apparently produced by a direct action on liver cells. The injection of small amounts of glucose into the artery supplying a pancreas grafted into the neck of a depancreatized dog or into the pancreatic artery in a decerebrate cat causes a prompt lowering of blood sugar. In the latter case the effect was not obtained when the splenic or portal vein was used. If these results can be accepted they provide evidence for the chemical control of insulin liberation through the action of the glucose on structures within the pancreas. The results of experiments with denervated pancreatic grafts indicate that the nervous control is not essential. The nerve impulses which affect the islet cells are apparently conducted by the vagus. Vagus fibres have been traced to the islet cells and non-medullated branches are said to pierce them. The results of stimulating the vagus *appeared* to be clear cut and the pathway was traced by one group of investigators to the hypothalamic region, but other workers have as yet been unable to confirm these findings.

Information on the factors controlling the secretion of insulin has accumulated very slowly. The finding of Houssay, Foglia and their collaborators that two or three pancreases from normal dogs, when introduced into the carotid-jugular circulation of a depancreatized dog, produce no more effect than one pancreas, is strongly indicative of a chemical control of insulin liberation. These workers have studied the rate of liberation of insulin from the pancreas of hypophysectomized dogs, and of dogs made transiently or permanently diabetic by anterior pituitary extracts. The findings in general conform to those obtained by

² There may be a constant liberation of a small amount of insulin.

studying the insulin content of pancreas in relation to the state of carbohydrate metabolism of the animal (p. 584). Neither of these methods yields information as valuable as that which will be obtained when the insulin content of blood, and the rate of pancreatic blood flow can be accurately determined in intact unanesthetized animals.

GENERAL EFFECTS OF INSULIN ON THE DIABETIC ORGANISM

It is well established that insulin restores to the depancreatized animal its ability to utilize sugars and fats in a normal manner. The excessive breakdown of protein is prevented. The ketosis rapidly disappears. Glycogen is deposited in large amounts in the liver. Muscle glycogen may be increased. The respiratory quotient rises when sugar is made available, or in fact when insulin alone is administered. Animals recover their ability to deal with infective agents. In brief, a well-treated depancreatized animal is difficult to distinguish from a normal one. There has been the difficulty, of course, that in the animal without a pancreas relatively large amounts of insulin are made available (by subcutaneous or intravenous injection) while in the intact animal small or large amounts are presumably liberated from the pancreas as the need arises. Adult depancreatized dogs on an adequate diet including the enzymes of the external secretion of pancreas have been maintained in good condition for more than four years (Macleod; Hédon; Bliss; Fisher).

THE MECHANISM OF ACTION OF INSULIN

In both the diabetic and the normal animal the level of blood sugar is lowered by the administration of insulin. The diabetic animal is more susceptible to insulin than the normal. In both the normal and the diabetic individual the oxygen consumption is increased and the R.Q. rises. This indicates that more sugar is burnt when insulin is provided. Small amounts of glycogen may be deposited in the muscles and liver of the depancreatized dog when no insulin is given but the administration of insulin produces a dramatic increase in the rate of glycogen deposition in both these tissues. In the normal animal one of the most clear cut effects of insulin is the increase in the rate of glycogen deposition in the muscle which it produces but it has not been demonstrated in any normal adult animal that insulin increases the level of liver glycogen. The increase seen in the livers of young rabbits is due to a secondary liberation of adrenaline. In the normal adult animal

there may be an actual loss of glycogen from the liver when insulin is administered. This is due to the accelerated glycogen deposition in muscle and the increased rate of oxidation of sugar.

There is now convincing direct evidence secured by the use of thermostromuhr technique for measuring blood flow to the liver and by blood sugar estimation, that the injection of insulin decreases gluconeogenesis in the liver. It will be appreciated that it was necessary to determine the blood flow as well as the concentration of sugar in the blood going to and flowing away from the liver before this fact could be established. One of the main effects of insulin, therefore, is exerted on the liver. It will be remembered that this tissue has first opportunity to utilize the supply of insulin which is secreted by the pancreas into the pancreatic capillaries and veins and thence by way of the portal system to the liver. It is also significant that the liver is responsible for a very large fraction of the total metabolic changes which take place in the body.

Insulin is, however, effective in the hepatectomized animal. In this preparation or in one from which all the abdominal viscera has been removed, the administration of insulin increases the deposition of muscle glycogen and the oxidation of sugar. In balanced experiments these two processes account satisfactorily for all the sugar which disappears. The action of insulin can also be demonstrated on the perfused leg of the cat or dog and it has now been shown that in the surviving diaphragmatic muscle of the rat suspended in oxygenated Ringer's solution containing glucose, the rate of formation of glycogen is increased when insulin is added to the solution. No effect of insulin on the oxygen consumption of this preparation has been demonstrated.

The addition of insulin delays the falling-off in respiration of minced pigeon-breast muscle and this effect can be demonstrated even without the simultaneous addition of citrate which was originally thought to be necessary. A greater effect was found when the muscles from depancreatized pigeons were used. This action has not yet been demonstrated in mammalian muscle. Insulin has been found to stimulate the respiration of baker's yeast under certain conditions.

In the depancreatized animal insulin decreases the lipemia and cholesterolemia and prevents the deposition of the large amounts of excess fat which accumulate in the liver in the untreated animal. The level of the ketone bodies in the blood is restored to normal. This effect may be due to a

diversion of metabolism from fat to carbohydrate. The formation of fat from carbohydrate is increased under the influence of insulin. It has been shown that insulin in the presence of fructose fumarate or lactate inhibits the formation of ketone bodies in liver slices of diabetic cats.

The excretion of nitrogen in the diabetic preparation is decreased by the administration of insulin. In the normal or diabetic animal the amino acids, urea, creatine and creatinine content of the blood are decreased by insulin administration. This effect which may be in part due to the secondary liberation of adrenaline, is also a direct action of the antidiabetic hormone. It has been reported that insulin increases the rate of utilization of amino acids by the muscles and that the synthesis of protein is accelerated. Undoubtedly a large part of the effect of insulin on protein metabolism, is due to a decrease in the rate of gluconeogenesis in the liver.

Insulin decreases the inorganic phosphate of the blood and there may also be a slight increase in the hexose phosphate content of muscle but this latter effect is due, in part at least, to a secondary liberation of adrenaline during the insulin hypoglycemia.³

Various changes in the concentration of the metallic constituents of the blood have been reported after insulin injection. These, and particularly that in the concentration of potassium, suggest a fundamental relationship between electrolyte and carbohydrate metabolism. The decrease in blood sugar produced by insulin is accompanied by a simultaneous fall in potassium.

It is now well established that the administration of insulin lowers the insulin content of the pancreas in fasting or fed animals. Furthermore it protects the islet cells against the degenerative changes which occur after the removal of a large part of the pancreas. Similarly the degenerative changes in the islets and the loss of insulin content produced by the administration of the diabetogenic substance of the anterior pituitary gland are prevented if insulin is supplied. If, after the diabetic state has been produced in partially depancreatized dogs by administration of diabetogenic preparations, insulin is given in adequate amounts, the diabetes may disappear. Thus insulin under these experimental conditions can both prevent and cure diabetes (Haist, Campbell and Best; Lukens and Dohan).

³ There is some evidence that the rate of turnover of certain of the phosphate compounds in muscle and the amount of adenosine triphosphate in liver may be increased by insulin.

As we have stated previously, small amounts of muscle glycogen may be deposited in the diabetic organism in the absence of insulin. When insulin is provided the rate of deposition of muscle glycogen is greatly accelerated. Insulin enables the body to effect this conversion at physiologic concentrations of blood or tissue sugar. It is of great interest, as mentioned previously, that the *in vitro* conversion of glucose to glycogen may be effected in the absence of insulin and that the addition of insulin exerts no effect. It follows from this finding that insulin may exert its effect on carbohydrate metabolism at some intermediate step between the hexose phosphate and the pyruvic acid. The dependence of the glycogen forming enzyme, phosphorylase, on the concentration of inorganic phosphate may be emphasized again here. Reactions which lower the concentration of inorganic phosphate i.e. the action of insulin, should stimulate phosphorylase activity in the direction of glycogen synthesis.

INTERFERENCE WITH THE ACTION OF INSULIN

Other hormones. There are five internal secretions the action of which may be considered to be antagonistic to that of insulin. There is no evidence of any chemical interaction of these hormones with the antidiabetic substance.

Enzymes. Insulin is destroyed by pepsin-HCl and by the activated proteolytic pancreatic enzyme. Pancreas may, however, be incubated aseptically at neutral or acid reaction without loss of the antidiabetic substance. Insulin is relatively unstable in alkaline solution. There is apparently an enzyme system in blood which is capable of inactivating insulin but its characteristics have not been extensively studied.

Reaction of tissues. Since insulin acts on the cells of the liver and muscles, factors which influence these tissues, acidosis for example, may modify insulin action. Furthermore, since the liver is so largely responsible for the regulation of blood sugar, influences affecting this organ may cause a change in sugar content quite apart from the action of insulin. A change in the acid-base equilibrium of the body toward the acid side renders injected insulin less effective, a change toward the alkaline makes insulin more effective.

Products of infection. The toxic products elaborated by many microorganisms may interfere with the action of insulin. There is experimental evidence (1) that the insulin content of pancreas is decreased in certain severe infections but this does not necessarily indicate a decreased rate of

liberation of the hormone, (2) that the suprarenal and thyroid glands are stimulated to release more of their internal secretions,⁴ (3) that the synthesis of glycogen from lactic acid in the liver is inhibited and (4) it now appears that normally liver glycogen is changed to glucose by the phosphorylating mechanisms discussed above. Amylase, which splits glycogen to dextrins, maltose and finally to glucose, does not have access to the liver cells. When certain toxins are administered, however, amylase activity can be demonstrated and this abnormal route of glycogen breakdown provides another mechanism by which the products of infection make the organism resistant to the action of insulin. Insulin has no effect on the activity of amylase. Certain toxins may act on one or more of these mechanisms but investigation of this field is still in the preliminary stages.

Anesthetics. All anesthetics interfere more or less with the action of insulin. More or less asphyxia is produced by all general anesthetics. In asphyxia (1) adrenaline is liberated and (2) acid products tend to accumulate. Chloralose and amytal cause the least disturbance of carbohydrate metabolism.

SUBSTITUTES FOR INSULIN

Insulin therapy has two obvious disadvantages (1) the transient effect and (2) the necessity for parenteral injection of the active material. The most important of the suggested substitutes is synthalin (decamethylenediguanidine). This substance does not increase deposition of glycogen and the effect on hepatic gluconeogenesis is accomplished in a highly unphysiological manner. Insulin is apparently the only agent which inhibits sugar formation without damaging liver cells. Extensive deposits of fat produced in diabetic dogs by fat feeding as well as by many chemical compounds other than synthalin interfere with sugar formation. It is preferable that the human diabetic organism should excrete some of the sugar made by a relatively healthy liver than to be made "sugar free" by damaging liver tissue so that less glucose is formed.

INSULIN REQUIREMENT AND ADMINISTRATION

Interesting studies have been made of the insulin requirements of depancreatized dogs under different conditions. Thus the blood sugar has been

kept at a normal level by simultaneous and continuous intravenous injection of insulin and dextrose solutions. The insulin required was between 0.06 and 0.4 units per kilogram per hour, while the corresponding requirement of dextrose was 0.2 and 0.6 gm. per kilogram per hour. The higher values for insulin and dextrose were those required by unanesthetized dogs; the others by anesthetized dogs. In another study the amount of insulin necessary to keep the blood sugar at a normal value in depancreatized dogs under basal conditions was between 0.005 and 0.035 units per kilogram per hour, with an average value of 0.017 units per kilogram per hour. The duration of action of insulin is not proportional to the size of the dose injected but is a simple function of the logarithm of the dose; i.e., insulin is inactivated in the body at a rate proportional to the amount in the body at the time. Thus if 1 unit lasts four hours, 10 units would last eight hours.⁵

Insulin may be administered effectively by the subcutaneous or intravenous route. Some absorption may be obtained by inunction or by application to the sublingual or other mucous surfaces. Rectal administration is ineffective. Studies continue to be made on the problem of the oral administration of insulin. Efforts have been made to combine it with various materials, dyes, phenolic substances, tannic acid etc. which might protect the protein molecule from destruction by the intestinal enzymes. The difficulties involved are obvious, and it is therefore not surprising that, while some success has attended these efforts in the laboratory, no satisfactory application to the treatment of diabetic patients has yet been made.

MODIFIED INSULIN

One of the most obvious difficulties in the use of regular insulin in clinical diabetes is its transient and sometimes too violent action. This difficulty has been much more frequently encountered since the highly purified preparations of insulin have been made available. The cruder products were absorbed more slowly. While a great many attempts have been made to slow and prolong the action of insulin, the first important success has been obtained by Hagedorn, Jensen, Krarup and Wodstrup. These investigators have shown that a compound of insulin with any one of several protamines exerts a slower and more prolonged

⁵ Several observers have now suggested that the insulin requirement for the completely depancreatized human subject is less than that of many severe diabetics. These studies are difficult to control and final judgment on this important point must be reserved.

⁴ The first effects of the products of infection may be to excite liver tissue to increased gluconeogenesis and discharge of glucose. Later the liver cells may be damaged so that less glucose is produced.

anti-diabetic effect than regular insulin. This has been shown by microscopic observation (Beecher and Krogh) to be due to the much slower absorption of the insulin combined with protamine than is the case with the regular preparations of this substance.

The incidence of hypoglycemic reactions when protamine insulin is used is much less than with regular insulin. The blood sugar level is much more constant and the patient is maintained in a more physiological state. The clinical findings of the Danish group have already been abundantly confirmed.

Completely depancreatized dogs may be maintained sugar free, while receiving a very liberal diet, on one dose of protamine insulin daily without the development of any hypoglycemic reactions (Kerr and Best).

Scott and Fisher have demonstrated that protamine insulin is greatly improved by the addition of a small amount of zinc. The resulting product, protamine zinc insulin, exerts a more prolonged hypoglycemic action and forms a much more stable suspension than protamine insulin. In the United States and Canada about 55 per cent of the total insulin used is now in the form of protamine zinc insulin.

Various other forms of modified insulin have been prepared and tested clinically. Histone insulin and globin insulin are examples. Clinical opinion is still largely in favor of protamine zinc insulin.

HYPOGLYCEMIA

Under certain exceptional circumstances hypoglycemia may be produced by excessive utilization of glucose (prolonged very violent muscular exercise) but interference with the formation of sugar in the liver is largely responsible for most types. The three main factors which diminish sugar production may be classified as follows: (1) abnormality of liver cells, (2) the inhibiting action of insulin on gluconeogenesis in the liver, and (3) the decreased hepatic gluconeogenesis resulting from diminished output of the anterior pituitary, thyroid, or cortical and medullary adrenal secretions. Under the first heading a great variety of experimental and clinical conditions may be listed—for example—phosphorus or hydrazine poisoning, yellow fever, acute yellow atrophy, and the bacterial infections. When the normal liver is completely removed, profound hypoglycemia occurs promptly. Approximately 80 per cent of the normal liver must be removed before hypoglycemia

is produced. Under the second heading we now consider *hyperinsulinism*. This term should be reserved for conditions in which it is established that there is liberation of excessive amounts of insulin from the pancreas. This has been the case in numerous instances in which the removal of a tumor of islet cells has corrected the hypoglycemia. Correction of the condition by removal of a large part of the pancreas does not prove that the cause was liberation of abnormal amounts of insulin since decreasing the amount of insulin may merely compensate for the first abnormality. Insulin as discussed above causes hypoglycemia by other mechanisms as well as by decreasing gluconeogenesis. The relative importance of the three glands of internal secretion listed under the third heading may vary in different species. Removal of the thyroid increases the sensitivity of an animal to insulin and the same is true of the adrenal medulla, but hypoglycemia is not produced. When the anterior pituitary is extirpated, however, there may be profound hypoglycemia and this finding suggests that diminished secretion of the diabetogenic substance may be an important factor in certain clinical cases in which the liver and pancreas appear perfectly normal. In some species removal of the whole adrenal gland causes hypoglycemia and this is, at least partially, corrected by the administration of cortical extract. Clinically certain cases of Simmond's disease (diminished anterior pituitary secretion) and of Addison's disease (involvement of adrenal cortex) may exhibit hypoglycemia. (See table 55.)

Signs and symptoms

The signs of hypoglycemia were first adequately described by Mann and his collaborators. The low blood sugars were produced in dogs by removal of the liver. The description of this condition enabled the Toronto investigators to recognize that the effects of large doses of insulin were the same as those due to hypoglycemia produced by other means. The signs and symptoms vary in the different species. The first signs in the rabbit are hyperexcitability and desire for food. The excitability becomes greater, and mild and then severe convulsions are exhibited. The head is retracted and the hind limbs extended in the intervals between convulsive seizures. Coma is frequent. The animals may exhibit rigor mortis immediately after death. The signs in dogs are quite similar. Mice, in some instances, may become comatose without exhibiting convulsions. Cold blooded animals do not show any signs until

	Surgical interference with blood flow	

There may also be excessive utilization of sugar by muscles—dogs in tread mill, marathon runners, etc.

* The term "hyperinsulinism" was introduced by Seale Harris in 1924 to describe cases exhibiting signs of hypoglycemia. The first report of a tumor of the islet cells which in this case had secondary growths in the liver was made by Wilder, Allan, Power and Robertson in 1927. Many cases of tumor have now been studied.

many hours or even days after insulin injections. The signs and symptoms in man have been ex-

tensively studied in the laboratory and clinic. The initial symptoms may be hunger or a feeling of nervousness—a sense of impending danger. A little later there may be profuse perspiration, alternate pallor and flushing of the face, vertigo and diplopia. The blood sugar at this stage is 0.06–0.04 per cent but the level varies greatly in different individuals. Most hypoglycemic reactions proceed no further than this. In very severe cases there may be delirium, convulsions, and death. The true blood sugar may decrease until only non-sugar-reducing power remains.

Sakel's insulin-shock treatment for schizophrenia has focussed attention on the metabolism of brain and the effects of prolonged hypoglycemia. Brain tissue utilizes carbohydrate almost exclusively. Hypoglycemia interferes with the supply and produces much the same condition as O₂ deficiency. The electrical activity of the cerebral cortex is depressed in hypoglycemia and restored to normal by the administration of glucose. The reduction in the oxidative metabolism of brain is undoubtedly responsible for this and other changes.

Cerebral damage, which may be permanent, has been observed in both animals and man as a result of prolonged hypoglycemia.

Alleviation of hypoglycemia

The intravenous administration of glucose is the most effective method of alleviating hypoglycemia. The prompt recovery of almost moribund animals provides one of physiology's most fascinating demonstrations. Mannose is almost as useful as glucose, and fructose also occupies a preferential position. Galactose and maltose have a slight but transient effect. Sucrose,⁶ lactose and pentoses are not effective. Glycogen and glycerol have been shown to exert some beneficial action. The effect of these substances in hypoglycemia is probably largely dependent on the rapidity with which they are transformed into glucose in the liver. Fructose may be converted slowly to glucose in muscle but there is a possibility that it may be burned directly (Griffiths and Waters). It is generally assumed that the only sugar directly oxidized in the muscle, where a large part of the total oxygen use takes place, is d-glucose. The usefulness of the other carbohydrates would therefore depend on the ease of their conversion into this sugar. Adrenaline and pituitrin may be used to alleviate hypoglycemia but glucose is much more

⁶ Carbohydrates which form glucose are, of course, effective. The above statement refers to the results of intravenous injections.

efficacious and safe. Liberation of adrenaline is, however, one of the physiological mechanisms by which hypoglycemia is corrected. Intense anger, such as that which might well be experienced by a diabetic whose hypoglycemia was mistaken for alcoholic intoxication (Duncan) may correct hypoglycemia through liberation of adrenaline.

THE INSULIN CONTENT OF THE PANCREAS UNDER DIFFERENT CONDITIONS

The insulin content of the pancreas has been determined in various animal species. The insulin is extracted from minced pancreases with an acid aqueous alcohol solution. Certain contaminating material is removed and the active material is precipitated. This is then redissolved and estimated by the mouse method of assay. In the dog the insulin content of the free splenic end of the pancreas is greatest, that of the attached duodenal portion has an intermediate value, while that of the free duodenal end is lowest, the values being about 4, 3, and 2 units per gram, respectively. In partially depancreatized dogs, provided sufficient pancreas is left to prevent the onset of diabetes, the insulin content does not differ from that of the corresponding part in a normal dog, nor are any degenerative changes in the β cells noted. If diabetes supervenes, hydropic degeneration of these cells is observed, and the insulin content of the remnant of pancreas falls to extremely low values. The daily injection into dogs of diabetogenic extracts from the anterior lobe of the pituitary gland produces a prompt and profound decrease in the insulin content of the pancreas (in seven days to 0.2 units per gram). If the injections are stopped at this stage, the insulin content is restored to normal within four days. If the administration is continued the insulin is reduced to negligible amounts. No recovery will occur when this point is reached. Simultaneous administration of insulin prevents or greatly modifies the fall in the insulin stores. This fact strongly suggests that the β cells are permanently damaged by the extract through overwork and that the simultaneous administration of insulin relieves the cells of some of this excessive demand for the hormone.

Starvation (seven days) or a diet rich in fat produces a decrease in the insulin content of the rat's pancreas to about half the normal value, which is about 24 units per rat. These animals have their insulin stores speedily restored to normal (in six days) when they are returned to a

balanced diet; carbohydrate alone effects a partial restoration. Daily injection of insulin into rat causes an even more marked decrease in the insulin content of the pancreas than does starvation (Haist and Best). Massive doses of insulin over prolonged periods may produce atrophic change in the pancreatic islets of partially depancreatized dogs which survive the treatment (Mirsky).

The injection of anterior pituitary extracts in certain strains of rats increases the islet volume and the insulin content of pancreas (Young Richardson and Marks). The effect of various hormones of the anterior pituitary on the insulin content of rat pancreas has been studied by Fraenkel-Conrat, Herring, Simpson and Evans. The purified lactogenic substance increased the insulin content in both normal and hypophysectomized rats. Growth hormone decreased the insulin content in normal and adrenalectomized animals but the effect could not be demonstrated after removal of the pituitary. Neither removal of the pituitary, the adrenals, nor the administration of cortical extracts changed the insulin content of the pancreas in the intact rat (Haist and Bell). It would appear probable, however, that cortical sterols which produce diabetes in normal animals will be found to lower the insulin content.

Subcutaneous estrogen transplants or the administration of stilbesterol produce an increase in the insulin content of rat's pancreas. This effect is not observed in the absence of the pituitary (Griffiths, Marks and Young; Funk). Stilbesterol may exert a diabetogenic effect in force-fed normal and partially depancreatized rats (Ingle).

The effect of age on the insulin content of the pancreas has been studied in the cow. In fetal calves under 5 months the concentration was 34 units per gram; in calves 6 to 8 weeks old, 10 units per gram; in heifers 2 years old, 5 units per gram; in cows over 9 years, 2 units per gram. Pregnant cows 7 years old and older showed no change from the normal insulin content of about 2 units per gram (Scott and Fisher). In Wistar rats the total insulin content of the pancreas increases with age.

Pancreases obtained from non-diabetic persons at autopsy have an average insulin content of about 2 units per gram. This is probably somewhat lower than the true value. Pancreatic tissue from diabetic persons shows wide variation, the average content of those studied being 0.4 units per gram.⁷ The insulin content of a tumor of islet tissue surgically removed from a patient suffering

⁷ These studies present great difficulties and much further work is needed to provide reliable data.

from hyperinsulinism may be as high as 214 units per gram.

It is, of course, apparent that these "insulin contents" indicate the balance between the rate of production of the hormone in the islets and the rate of liberation. There is good reason to believe that under certain conditions the rate of liberation is proportional to the content. Under other circumstances this may not be true. The conclusion has been drawn from some of these results that the islet cells are "rested" after administration of insulin, by starvation and by a high fat diet and that less insulin is excreted by the pancreas than under normal conditions. Partial pancreatectomy, sufficiently extensive to result in diabetes, or administration of diabetogenic extracts causes (1) marked stimulation of the islets and (2) subsequently degenerative changes and loss of insulin.⁸

THE USE OF INSULIN IN NON-DIABETIC CONDITIONS

Favorable results have been claimed for the use of insulin in a very great variety of non-diabetic conditions. It has been used in pernicious anemia, in acute infectious diseases, in eclampsia, in pernicious vomiting of pregnancy, and in hepatitis—to mention only a few. While it is conceivable that insulin might be of slight benefit in some of these conditions, it would appear that equally satisfactory results can be secured by the administration of glucose alone. It is a clinical fact that the administration of glucose produces favorable results in a variety of hepatic abnormalities. A high glycogen content protects the liver cells from damage and the inhibition of gluconeogenesis produced by both insulin and glucose may also play a role.

Insulin can now be considered, however, an established adjuvant in the treatment of certain cases in which lack of appetite prevents the ingestion of adequate amounts of food. The physiological basis for this use of insulin in these non-diabetic individuals rests very largely upon the increase in hunger and appetite which may be caused by the administration of sufficient material to produce a definite but not too marked hypoglycemia. In 1924 Bulatao and Carlson reported that production of hypoglycemia in experimental animals by the subcutaneous injection of insulin was uniformly accompanied by hypertonus and hypermotility of the stomach. The gastric tonic-ity and motility increase as the hypoglycemia deepens until complete tetanus is reached, which

persists until the dog exhibits hypoglycemic convulsions or until sugar is given. The effect of sugar is immediate, but if a large dose of insulin has been given the hyperactivity of the stomach returns as soon as the blood sugar falls again. The first record of the increase in gastric peristalsis in the human individual after insulin administration was that of Dickson and Wilson, 1924. An hour and ten minutes after the administration of insulin the tone, depth and rate of peristalsis and rate of emptying of the stomach were definitely increased. This condition persisted for two hours, when the blood sugar was found to be 70 mgm. per 100 cc. Glucose was then given, and while the acute symptoms were definitely relieved the hunger persisted. Subsequently Quigley, Johnson and Solomon studied the effect of insulin on the gastric movements of four human subjects. They found that doses of from 12 to 20 units of insulin definitely increased the gastric activity. The first definite augmentation was observed about an hour after the injection and persisted for at least five hours. There was prolonged duration of the hunger period, and this was considered to be the most characteristic effect of insulin. The increased peristalsis produced by insulin is not inhibited by such procedures as smoking, unpleasant emotions, body discomfort, or the presence of moderate amounts of non-carbohydrate food in the stomach. The increased movement was inhibited by atropine. The immediate relief of the excess peristalsis and hunger when appropriate amounts of glucose were given was confirmed.

It is known that insulin does not exert its effect on gastric motility and secretion after section of the vagus nerves. This means that either insulin acts centrally by stimulating the vagus, or that the continued elaboration of acetylcholine, which we now know is an essential part of the mechanism by which the vagus exerts its action, provides a foundation upon which the peripheral effects of insulin may be superimposed.

Insulin augments also, to some extent, peristaltic movement in the duodenum and in the colon, but the effect is not as marked as in the case of the stomach. It will be remembered that one of the early symptoms observed in experimental animals and also in human subjects after the administration of insulin is an increase in hunger. In animals an attempt to consume material of little nutritive value which under ordinary conditions they would not attempt to eat is often observed. It would appear, therefore, that the clinician is able to take advantage of this situation by providing nutritious food for his hungry patient. The increase in weight observed in both animals and patients when appropriate doses of insulin are given for prolonged periods is due

⁸ For references to work on insulin content of pancreas, see Haist, 1944.

to increased deposition of fat, and possibly also to a slight extent by increased deposition of carbohydrate. The increase in weight is not attributable to any appreciable extent to the retention of water.

INFLUENCE OF OTHER ENDOCRINE GLANDS ON CARBOHYDRATE METABOLISM

The adrenals

The glucosuria produced by adrenaline was first noted by Blum. The intravenous route of administration gives the greatest rise of blood sugar but subcutaneous, intramuscular or intraperitoneal injections are effective. The immediate rise in the sugar of the blood is due to breakdown of liver glycogen to glucose. There may be a considerable decrease in the amount of liver glycogen. Adrenaline also mobilizes muscle glycogen (Cori) but here the immediate product is lactic acid and not glucose. A part of the lactic acid is carried by the blood to the liver where it is converted to glycogen, which in turn furnishes the blood with glucose. Muscle glycogen is therefore available indirectly to replenish blood glucose. When lactic acid from the muscles has been changed in appreciable amounts to glycogen in the liver the amount of substance in this organ may be increased over the normal level. Adrenaline therefore in moderate dosage, first causes a decrease and then an increase in liver glycogen. Very large doses over prolonged periods may lower both muscle and liver glycogen. The nervous control of adrenaline secretion has been discussed on page 689, and the manner in which thoracic autonomic impulses may affect blood sugar through its liberation will be appreciated. Adrenaline does not accelerate sugar formation from other substances in the liver. Diabetes has not been produced by the continued administration of adrenaline.

Insulin and adrenaline are not chemical antagonists but possess opposing physiological actions. Adrenaline accelerates the breakdown of both liver and muscle glycogen but the lactic acid made from muscle glycogen may result in an actual increase in the liver. Insulin promotes the formation of glycogen in both organs but the increase in muscle glycogen may be at the expense of sugar which would have formed liver glycogen. These are excellent examples of the manner in which the action of a hormone may be obscured by other effects. When the blood sugar is lowered to about 0.06 per cent by insulin an increased rate of liberation of adrenaline may be detected (Cannon; Houssay). Adrenaline has also been reported to

increase the rate of liberation of insulin from the pancreas.

There are several investigations the results of which have been interpreted to mean that adrenaline inhibits carbohydrate oxidation in the muscle. The evidence, fall in R.Q. when adrenaline is added to an intravenous injection of glucose, might also indicate an increased formation of sugar from fat. Adrenaline has not been shown to depress carbohydrate oxidation in the liverless preparation.

THE ADRENAL CORTEX AND CARBOHYDRATE METABOLISM. After double adrenalectomy in some species (cat and rat) the carbohydrate reserves of the liver and muscles are depleted and there may be definite hypoglycemia (Britton and Silvette). These workers showed that the hypoglycemic condition may be corrected when the cortical hormone and glucose are provided but not when the latter alone is given. They reported that the administration of extracts of the cortex elevated the carbohydrate stores of adrenalectomized animals well beyond the normal limits. Insulin and glucose do not increase glycogen deposition in the adrenalectomized animal unless cortical extract is supplied (Britton) but it is possible that this effect might occur if the animals were supplied with a diet adequately low in potassium and high in sodium. Long and his collaborators have extended the earlier experiments of Britton and Silvette and find rather remarkable increases in liver glycogen in fasted or fed normal animals when extracts of the adrenal cortex were administered. Muscle glycogen was not affected by the cortical material in these experiments but may be increased when adequate amounts of sugar are supplied. Corticosterone and dehydrocorticosterone had the same effect as cortical extract.

After Houssay's demonstration that removal of the pituitary gland attenuates the severe diabetes resulting from total pancreatectomy in the toad and dog, Hartman and Brownell, and Long and Lukens, showed that a very similar change could be produced by adrenalectomy in the depancreatized cat or dog. It has been shown by Lukens and Dohan that the diabetes of adrenalectomized depancreatized animals and also that of hypophysectomized depancreatized animals can be increased in severity by the injection of cortical extracts.

Long, Katzin and Fry have shown that the rat, partially depancreatized by the method of Shapiro and Pincus, is an excellent preparation for the demonstration of the role of the adrenal cortex in

carbohydrate metabolism. Adrenalectomy attenuates the diabetes which may be observed in these animals. The grafting of cortical tissue may restore the glucosuria to the extent which has been observed before adrenalectomy.

The relative potency of various adrenal steroids has been studied by Long and his collaborators, by Kendall and by Ingle and Thorn. The carbohydrate levels of the body are restored and the glucosuria of partially depancreatized or adrenalectomized partially depancreatized animals is augmented to the greatest extent by corticosterone and its derivative with an hydroxyl or ketone group at C₁₁. Cortin has a somewhat favorable effect on carbohydrate storage but 11-desoxycorticosterone has very little action in the dosage which is effective in the maintenance of life and mineral balance in adrenalectomized animals. In much larger amounts it may exert some favorable influence. The injection of 5 milligrams a day of 11-dehydro-17-hydroxycorticosterone is followed by glucosuria, ketonuria and an increased excretion of nitrogen, phosphorus and potassium in partially depancreatized rats. Ingle has recently reported that the dehydro compound in doses of 10 milligrams a day may produce hyperglycemia and glucosuria in normal rats. It is established, therefore, that these adrenal compounds may be very powerful diabetogenic agents.

It has been shown by Long and his collaborators and by Ingle and other workers that the mechanism through which these adrenal extracts produce glucosuria is by stimulating gluconeogenesis from protein but as the increase in nitrogen excretion is insufficient to account for the extent of the glucosuria, interference with glucose oxidation has also been postulated.

Some but not all of the abnormalities of carbohydrate metabolism in adrenalectomized animals are apparently due to the disturbance in sodium and potassium metabolism. Thus the delayed absorption of sugar and fat and the failure to store glycogen from glucose can be favorably affected by appropriate salt treatment. On the other hand the sharp fall in carbohydrate levels in fasting adrenalectomized animals and the amelioration of diabetes in partially depancreatized rats by adrenalectomy are not corrected by feeding sodium salt but are by the administration of suitable cortical material.

The question arises as to how much of the diabetogenic action of the anterior pituitary gland is exerted through the adrenal cortex. The evidence on this point is somewhat conflicting. It would

appear that the pituitary preparation may exert some diabetogenic action in the absence of the adrenal. The presence of some cortical hormone is, however, necessary for the action of the pituitary factor which acts independently of the adrenal. A part of the pituitary effect is undoubtedly exerted through the adrenal cortex.

Many of these findings which have been obtained on experimental animals, have been confirmed by Thorn and his colleagues in studies on patients with Addison's disease.

The pituitary and carbohydrate metabolism

It has been appreciated for many years that abnormalities in carbohydrate metabolism may be associated with acromegaly of long standing or with the presence of various pituitary tumors. In 1908 Borchardt found that an extract of the posterior pituitary raised the blood sugar. In 1911 Cushing observed that "pituitary deficiency" may be accompanied by an increased carbohydrate tolerance. When insulin became available Burn demonstrated an antagonism between "puititrin" and insulin, and several workers (Olmsted; Geiling; Houssay) showed that animals were more sensitive to insulin after removal of the pituitary body.

It appeared for a time that both the oxytocic and pressor principles of the posterior lobe produced hyperglycemia and thus interfered with the action of insulin. The work of Ellsworth and others indicates that the oxytocin is probably the more important factor from this viewpoint but it is doubtful, from the dosage necessary to produce the effect, whether this is of physiological significance. Griffiths has reported that posterior lobe extract, i.e., the vasoconstrictor principle, interferes with the absorption of insulin. The action of subcutaneously administered insulin is inhibited but when the intravenous route is used this effect is not observed.

In recent years interest has been focussed on the anterior lobe of the pituitary by the brilliant researches of Houssay and his collaborators and of other investigators. The main points established in Houssay's laboratory are as follows: (a) Removal of the anterior lobe of the pituitary increases the sensitivity to insulin of the normal animal and diminishes the intensity of diabetes in the depancreatized animal. (b) Injections of preparations from the anterior pituitary into normal or hypophysectomized animals diminish their sensitivity to insulin and increase the severity of the diabetic state in hypophysectomized-depancreatized (Houssay) animals. (c) The administration of a suitable

extract of the anterior pituitary can induce a diabetic condition. This point was independently established by the reports of Evans and his colleagues and of Baumann and Marine, which preceded that of Houssay.

The effects of pancreatectomy and hypophysectomy are contrasted in the following summary, and the condition of the animal from which the pancreas and the pituitary have both been removed is briefly described.

<i>Pancreatectomy (Dog)</i>	<i>Hypophysectomy (Dog)</i>
Hyperglycemia	Low blood sugar, hypoglycemic convulsions during fasting
Polyuria	
Glycosuria	
Ketonuria	
Azoturia	
Insulin necessary for survival	Greatly increased sensitivity to insulin
Metabolic rate normal or slightly raised	Low metabolic rate
Decreased ability to utilize carbohydrate	Carbohydrate furnishes increased proportion of fuel
Decreased ability to form glycogen	Rapid disappearance of liver and muscle glycogen due to utilization of carbohydrate and decreased gluconeogenesis. ⁹
Increased gluconeogenesis	

Pancreatectomy and hypophysectomy

Animals survive without insulin. Polyuria, glucosuria, ketonuria, azoturia slight or absent. Administered carbohydrate partially or completely retained, i.e. carbohydrate utilization much better than in depancreatized dog. Metabolic rate low. Glycogen deposition.

PERMANENT DIABETES. The anterior pituitary gland contains a number of substances which affect carbohydrate metabolism in a variety of ways. These will now be considered briefly. Evans, Meyer, Simpson and Reichert in 1932 demonstrated the production of a prolonged diabetes in normal intact animals by anterior pituitary extract. F. G. Young, 1938, was however, the first to produce a permanent diabetes comparable in intensity to that resulting from complete pancreatectomy, by injection of extracts of the anterior lobe of the pituitary. He has found, in a very large number of dogs, that he is able consistently to produce a permanent state of diabetes by the daily injection, either intraperitoneally or subcutaneously, of a preparation of anterior lobe material. The per-

manent state of diabetes may be produced after as few as eleven daily injections but more are usually required. The diabetogenic activity, that is, the active material which will produce permanent diabetes in dogs, is associated with the globulin and pseudoglobulin fraction of the pituitary extract. The active principle is not available as yet in a pure state and it is notable that it possesses very distinct growth-promoting activity. Young's work has been confirmed by Campbell and Best and by Dohan and Lukens and many others. Degenerative lesions of the islet cells of the pancreas were first noted in these permanently diabetic animals by Richardson and Young. Signs of proliferative changes in the islet cells in the early stages of the injections were found by these workers and by Ham and Haist who also observed proliferative changes in the acinar and duct cells of the pancreas. The diabetogenic extract produced proliferative changes in various other glandular tissues in the body. Campbell and Best noted that the diabetic state produced by the pituitary extract was not intensified by complete removal of the pancreas and secondly, that the insulin content of pancreas was reduced to a negligible quantity. This latter point has been discussed elsewhere.

It would appear that the main effect of the substance or substances which produced the permanent diabetes is exerted upon the Islands of Langerhans. These cells are apparently first stimulated and then destroyed by the repeated injections of the active material.

The permanent diabetes produced by the above procedures differs from that caused by pancreatectomy, in that the animals may live for long periods without the administration of insulin. In some cases, however, insulin is required. Starvation or a diet very rich in fat causes a marked diminution in the intensity of diabetes in the permanently diabetic animal. The prolonged administration of crude diabetogenic preparations may produce a refractory state which is due to the appearance of an antistubstance (Lukens and Dohan) but it is unlikely that this will appear when a highly purified substance is used.

The production of permanent diabetes by the diabetogenic substance of the anterior pituitary, can be prevented by the simultaneous administration of large doses of insulin (Haist, Campbell and Best). The islet cells are protected from profound degenerative changes, the insulin content of the pancreas remains at a moderately high level, and the state of permanent diabetes is not induced.

⁹ For direct evidence of this effect see Crandall and Cherry.

Lukens and Dohan have shown that permanent diabetes produced in partially depancreatized cats by administration of the diabetogenic substance of the anterior pituitary gland, can be cured by the use of insulin, by a reduction in the caloric value of the diet or by an increase in its fat content. Recovery from early diabetes has followed a reduction in the diet only when the diabetes was very mild but treatment with insulin produced recovery at this stage regardless of the severity of the disease. If treatment were delayed until after the Islets of Langerhans had become atrophic, no recovery was possible.

It is to be noted that in the prevention and cure of this experimental diabetes, the level of the blood sugar is probably the most important factor which determines the direction in which the islet lesions will progress. This interpretation is supported by all the results which Young; Haist, Campbell and Best; and Lukens and Dohan have obtained and is in line with the earlier studies of F. M. Allen, Copp and Barclay and others.

THE GLYCOTROPIC OR ANTI-INSULIN ACTION OF ANTERIOR LOBE EXTRACTS. It was first demonstrated by Houssay and Potick and adequately confirmed by many later investigators that treatment with anterior lobe extract can induce in either normal or hypophysectomized animals an insensitivity to the action of insulin.

Bennett observed hyperglycemia and increased liver glycogen values upon prolonged administration of the adrenotropic hormone. Jensen and Grattan, and Ingle have shown that the adrenotropic substance as well as extracts of the adrenal cortex, and crystalline corticosterone produce a definite glycotropic effect. The adrenocorticotrophic factor failed to produce this anti-insulin effect or to promote deposition of liver glycogen in adrenalectomized mice. These findings, therefore, strongly suggest that the glycotropic effect of anterior pituitary extracts is due to the adrenocorticotrophic factor and that the anti-insulin action is due to the storage of large amounts of glycogen in the liver. This glycogen is presumably available to counteract the hypoglycemic effect of insulin.

THE GLYCOSTATIC EFFECTS OF ANTERIOR PITUITARY EXTRACTS. It is well established that hypophysectomized animals are unable to preserve their glycogen stores as normal animals do during fasting. It has been found by Russell and Bennett that this function can be restored, under certain conditions, by anterior pituitary extracts. In subsequent experiments it has been shown that this

action is not through the adrenal since muscle glycogen can be maintained at a normal level in the absence of both adrenal glands. The existence of a separate glycostatic factor has been postulated since the action is not associated with any of the established anterior lobe substances and a unit of glycostatic activity has been suggested in terms of the minimal dose necessary to maintain normal muscle glycogen in hypophysectomized animals. Russell's finding that, although this action is not exerted through the adrenals, it is greatly increased by the presence of cortin, may lead to very important developments.

THE PANCREOTROPIC ACTION OF ANTERIOR PITUITARY EXTRACTS. In 1933 Anselmino, Herold and Hoffmann reported that frequent injections of anterior lobe extracts in rats produce in a few days an increase in the size and number of the Islets of Langerhans. Richardson and Young were not able to confirm the findings under the conditions defined by the German investigators. They were, however, able to show that the daily treatment of rats with crude anterior pituitary lobe extract for a period of two weeks doubled the amount of islet tissue in the pancreas. More recently Marks and Young showed that the insulin content of rat pancreas was greatly increased under these conditions. (See Insulin Content of Pancreas.)

Mirsky and Swadesh have suggested that the influence of the pituitary gland on growth may be dependent on its pancreotropic function.

It will thus be apparent that the effect of the anterior pituitary gland on carbohydrate metabolism is exerted through a variety of mechanisms. The diabetogenic action which is in large part due to destruction of the Islets of Langerhans, produces its effect by eliminating the antidiabetic hormone, insulin. The action of this substance can therefore be described by enumerating those changes which are due to the absence of insulin from the body. The glycotropic or anti-insulin substance exerts its effect through the adrenal cortex. This action is primarily on the deposition of glycogen in the liver. The action of anterior pituitary hormones in the production of diabetes is more extensive than this. The work of Long and his collaborators has shown that diabetes may be produced in the partly depancreatized rat by administration of these substances but the extent to which the diabetogenic substance of the anterior pituitary affects the pancreas through the adrenal cortex, has not as yet been established. The glycostatic substance by immobilizing glycogen in the muscles may also contribute to the diabetic effect. Sup-

pression of carbohydrate oxidation by anterior lobe extracts has also been postulated but it is difficult to separate this effect from diminished gluconeogenesis in the intact animal. Direct evidence in favor of this suppression is, however, accumulating.

The anterior pituitary glands also affect carbohydrate metabolism through the thyrotropic and perhaps also through the gonadotropic substances. Removal of the adrenal cortex, thyroid, or the gonads produces histological changes in the anterior pituitary but the functional significance of these is not as yet clear.

Inhibition of the anterior pituitary effect on carbohydrate metabolism by the use of X-rays or by injection of estrogenic substances can be demonstrated in animals and in man but little of practical clinical value can be expected from these procedures.

The thyroid and carbohydrate metabolism

The aggravation of diabetes in man by hyperthyroidism and its amelioration by removal of the thyroid establishes a link between this gland and carbohydrate metabolism. It is surprising that very little influence on the diabetes of depancreatized animals can be demonstrated by thyroidectomy. This may be due in part to incomplete removal of thyroid tissue. When very extensive atrophy of the thyroid is produced by hypophysectomy in dogs, the blood sugar and a normal level of urinary nitrogen can be maintained for long periods during fasting if thyroxin is supplied. Without it hypoglycemia may soon terminate the experiment. Thus it appears that the thyroid may play a role in the effect of the anterior pituitary on carbohydrate metabolism. The slight effect of thyroxin administration on the intensity of pancreatic diabetes in animals still requires explanation.

The administration of thyroid substance or of thyroxin has no immediate effect on blood sugar but a loss of liver glycogen may be demonstrated within six hours. There is also apparently a rise in the protein content of liver pituitary perhaps to mobilization from peripheral tissues. Increased gluconeogenesis from protein can be readily demonstrated when thyroid substance is fed. An increase in the d-amino-acid oxidase activity of liver has been reported.

In clinical hyperthyroidism a mild hyperglycemia and glucosuria may be present. A comparable condition may be produced in animals by administration of thyroid material. At this stage liver glycogen is easily mobilizable (the actual amount present may be less than normal) and

adrenaline elicits more hyperglycemia and insulin less hypoglycemia than normally.

When thyroid feeding is continued there is profound decrease in liver, muscle and heart glycogen. In this second stage the animals are resistant to adrenaline and extremely susceptible to insulin. They may exhibit spontaneous hypoglycemia and develop it as a secondary result of a small injection of dextrose. This latter effect may be due to the liberation of insulin the action of which is not buffered by liver glycogen.

Thus the effect of the thyroid on carbohydrate metabolism is the resultant of two actions (1) increased oxidation of carbohydrate in tissue generally, and (2) the increased rate of hepatic gluconeogenesis.

THE NERVOUS REGULATION OF CARBOHYDRATE METABOLISM

As is the case with many other aspects of carbohydrate metabolism Claude Bernard paved the way for the investigation of the influence of the nervous system. Bernard (1855) punctured the floor of the fourth ventricle in unanesthetized animals and observed that the piqure produced a prolonged glucosuria. (The blood sugar of a rabbit may rise to 0.40 per cent within an hour and the effect may persist for several days or longer.)

It has been appreciated for some time that lesions in the hypothalamic region may cause glucosuria and the relation of these lesions to pituitary secretion has been in doubt. While lesions in this region might interfere with the absorption of the pituitary hormones or more likely, stimulate or destroy the nerve fibers going to the gland, it has been established that stimulation of the thoracic autonomic center in the hypothalamus may produce hyperglycemia. This gave rise to the idea that lesions lower in the brain stem might act by irritating the fiber tracts from the thoracic autonomic center but the situation is apparently not so simple. Donhoff and Macleod attribute special significance to the pons and there may be various centers, the impulses from which affect the level of blood sugar by more or less indirect paths.

There appears to be no doubt that Bernard's puncture damaged the cerebellum and also involved the pons. The nerve tracts affected are not accurately known but Donhoff and Macleod find that injury to the pons or the medulla immediately adjacent is essential for the development of hyperglycemia following decerebration. It ap-

appears probable that irritation setting up nerve impulses is responsible for the hyperglycemia rather than the interruption of nerve pathways. Decerebration above the pons does not produce hyperglycemia. The mechanism of action of the nerve impulses set up by the piqure is not entirely settled but several investigators find little response after removal of the suprarenals. The fact, however, that stimulation of the nerves in the hepatic plexus after removal of the suprarenals or of the nerves in the cut hepatic pedicle produces hyperglycemia by breakdown of liver glycogen, provides a mechanism for the more direct action. It appears probable as Macleod and Pearce suggested that while nerve impulses passing directly to the liver produce glycogenolysis, the presence of the adrenals may be necessary to maintain the integrity of the glycogenic nerve fibers. Glycogenic impulses are apparently conveyed by both the thoracic autonomic and the parasympathetic systems but the former are usually the more effective. This is particularly marked when animals with good supplies of liver glycogen are studied.

It will be appreciated that lesions of the brain involving (1) the pathways which carry glycogenolytic impulses to the liver or (2) the tracts which supply the adrenals, pancreas or pituitary may cause serious disturbances of carbohydrate metabolism. The first report of the production of such changes following lesions in the hypothalamus was made by Aschner in 1912. In recent years the subject has been studied by Keller and by Ingram and their collaborators. Stimulation of the posterior hypothalamic nuclei produces a hyperglycemia through the sympathico-adrenaline mechanism. Lesions of the paraventricular nuclei cause increased sensitivity to insulin and a prolonged hypoglycemia. Lesions of the tuber cinereum in the lateral hypothalamic area act in the same way as hypophysectomy in ameliorating the diabetes produced by pancreatectomy.

GLUCOSE TOLERANCE CURVES

When glucose is administered by mouth to a normal animal the blood sugar begins to rise within two or three minutes. This indicates that the sugar solution passes rapidly through the stomach to the duodenum. If large amounts of sugar are provided there may be considerable loss in the urine, i.e., *alimentary hyperglycemia* and *glucosuria*. After the usual meal, however, the hyperglycemia is not sufficient to produce glucosuria. When moderate amounts of sugar are given the rise in blood sugar is transient and the

return to the normal level rapid. This phenomenon is extensively used to test carbohydrate tolerance. The factors which determine the shape of the curve when from 50 to 100 grams of sugar are given by mouth are: (1) The rapidity of absorption, (2) the extent of the storage and utilization of glucose by the tissues, and (3) the rate of discharge of sugar from the liver. The first factor may, of course, be eliminated by injecting the sugar intravenously.¹⁰ The reaction of the tissues and of the liver to injected sugar may be direct or indirect. When more sugar is presented to the tissues more is utilized even though the insulin available remains constant. When the blood sugar rises the liver may discharge less sugar (Soskin, Allweiss and Cohn). The hyperglycemia may affect the liver and other tissues indirectly by increasing the insulin output and perhaps by other endocrine adjustments. The insulin liberated increases the oxidation and storage of glucose and decreases gluconeogenesis. An abnormal curve may indicate inability of the liver or pancreas, or of both to perform their normal functions. It might be due in part or completely to defective oxidation and storage in the muscles. It must be emphasized that an abnormal glucose tolerance curve *does not* necessarily indicate a deficiency of available insulin.

Undernutrition and carbohydrate metabolism

In 1873 Lehmann and in 1877 Claude Bernard noted a glucosuria in fasting animals after the administration of carbohydrate, and in 1890, Hofmeister, who made the first quantitative studies, named the condition "hunger diabetes". Utilization of carbohydrates is at a maximum in animals which have been fed on diets rich in these substances. After periods of fasting or of fat feeding, there is a definite impairment of glucose utilization which may easily be detected by the results of a glucose tolerance test. The feeding of an exclusively fat diet produces effects on glucose utilization indistinguishable from those of complete starvation. Proteins exert an effect intermediate between that of sugar and fat, i.e., some impairment of glucose utilization is produced by an exclusively protein diet. Diets adequate in other respects but providing a low caloric intake cause little disturbance in carbohydrate utilization. The administration to animals or human subjects

¹⁰ Normal dogs may be given 0.85 gram of glucose per kilogram per hour for long periods (Woodyatt) without producing glucosuria. This is approximately the same value as the maximum rate at which glucose is absorbed from the intestinal tract.

exhibiting hunger diabetes of a diet containing glucose causes a prompt improvement in carbohydrate tolerance.

The mechanisms of production and alleviation of the defect in carbohydrate utilization produced by fasting are not as yet completely elucidated. It would appear from the recent findings of Chambers, Cori and others that oxidation of glucose in the tissues is interfered with to a much greater extent than is glycogen formation. It has been established that the administration of insulin effects a partial restoration of carbohydrate utilization (Cori and Cori; Dann and Chambers). This finding suggests that insulin liberation may be depressed in hunger diabetes. Himsworth feels that a change in sensitivity to insulin is involved rather than a diminution of pancreatic output. On the other hand, the recent observation by Haist, Ridout and Best shows that the insulin content of the pancreas of rats may be reduced to nearly half the normal value by starvation or by fat feeding. This finding in conjunction with others supports the view that insulin liberation may be decreased. The evidence, which has been well reviewed by Chambers, does not indicate that the complete explanation of hunger diabetes will be found in the abnormal response of any one organ or tissue.

GLYCOGEN DISEASE. A clinical condition characterized by the enlargement of one or more organs resulting from the accumulation of glycogen has recently attracted the attention of research workers. The disease usually bears the name of von Gierke who published an autopsy report on a case in 1929. Van Creveld, in the previous year, had concluded that the hepatomegaly which he observed in a young boy was probably due to excessive glycogen deposition. The glycogen deposits may be in the liver, kidney, heart or in other tissues. The disease is characterized by hypoglycemia and ketosis in the fasting condition, by an abnormal effect of adrenaline which causes only a slight rise in blood sugar and lactic acid but a large increase in ketosis, and by an increased sensitivity to insulin. The glucose tolerance test gives a prolonged hyperglycemia without glucosuria. The glycogen content of the blood is increased and van Creveld noted a resistance of this material to glycogenolysis, but Schönheimer found no

abnormal properties of glycogen isolated from the liver or kidneys. The glycogen in these tissues does not, however, disappear at a normal rate after removal from the body and an interference with the glycogenolysis process is therefore indicated. The new knowledge of the steps by which glycogen breakdown proceeds makes possible many new and potentially important studies.

It would appear probable, as van Creveld has suggested, that glycogen disease is a continuation in childhood of a fetal condition in so far as certain aspects of carbohydrate metabolism are concerned. There are large deposits of liver glycogen in the fetus and this material is resistant to the action of adrenaline. It is well established that in some species the fetal pancreas at or near term, contains very high concentrations of insulin. Hyperinsulinism may produce excessive deposits of glycogen in well-fed animals and ketosis under fasting conditions. It has been suggested that the secretion of the anterior pituitary gland makes liver glycogen more resistant to breakdown. There are therefore various physiological leads to be followed in the attempt to elucidate the etiology of glycogen disease.

ALLOXAN DIABETES. This new type of experimental diabetes was first produced by Dunn, Sheehan and McLetchie (1943) who showed that alloxan has a selective necrosing action on the Islands of Langerhans. In 1937 Jacobs had noted the effect of alloxan in rabbits—an initial hyperglycemia and a subsequent hypoglycemia. No histological studies were made and Jacobs postulated an insulin-like action of alloxan. It has now been shown that the hypoglycemia is due to the liberation of insulin from the damaged islets and the diabetic state is caused by a failure of these cells to produce insulin. The diabetic action of alloxan has been demonstrated in the rabbit, rat, cat, monkey and dog. An attempt has been made to destroy the islet cells in advanced cases of hyperinsulinism in man by the administration of alloxan. Lesions in the liver and kidney, less marked than those produced in the islets, are seen in some species after the injection of this chemical.

There is, as yet, no evidence that alloxan has any physiological significance. A substance resembling it was reported, many years ago, in the urine and intestinal mucus in certain pathological conditions in man. Alloxan provides a convenient means for producing pancreatic diabetes, particularly in small animals which can not readily be depancreatized, and will thus be a most useful tool in the study of the diabetic state.

CHAPTER LI

FAT METABOLISM

CLASSIFICATION OF THE FATS AND FATTY SUBSTANCES OCCURRING IN THE BODY

When a tissue is thoroughly extracted with ether and alcohol almost all of the fatty substances are removed.

The amount of fatty acids combined in the cerebrosides and phospholipids may be determined by taking advantage of the insolubility of these materials in acetone to which some magnesium chloride has been added. The fatty acids may then be liberated and estimated by one of a variety of procedures. An estimate of the amount of the phosphorus containing substances can be obtained by determining the phosphorus content of the extract and similarly with those containing carbohydrate by estimating the sugar. The fatty acids combined with cholesterol can be determined by estimating the amount of bound cholesterol. The free cholesterol is removed by precipitation with digitonin and estimated gravimetrically or by colorimetric means. In another sample of the extract the bound cholesterol is liberated by saponification as with sodium ethylate and the total cholesterol determined. The difference between the free and the total is the amount of cholesterol combined with fatty acid and this can be calculated from the known combining weight of fatty acids with cholesterol. The result is an estimate of the amount of cholesterol ester. The difference between the total fatty acid content and the sum of the amounts combined with carbohydrate, phosphoric acid, and cholesterol, gives us an estimate of the amount combined with glycerol. The fatty materials or lipids may therefore be classified as follows:

(1) *Fats*. Esters of fatty acids and glycerol.

(2) *Lipoids*.¹

(a) *Phospholipids*. (Phosphatides).

Fatty substances containing fatty acids, phosphoric acid and nitrogenous groups (lecithin, cephalin and sphingomyelin).

(b) *Cerebrosides*. (Glycolipids). Combinations of fatty acid, sugar and a nitrogenous substance (phrenosin, kersin, etc.).

(c) *Waxes*. Esters of fatty acids and certain alcohols (but *not* glycerol), (cholesterol esters, beeswax, etc.).

(3) *Sterols*. Hydrogenated phenanthrene derivatives (free cholesterol, ergosterol, etc.).

(4) *Hydrocarbons*. (Squalene, carotene, etc.).

The triglycerides

CHEMICAL STRUCTURE. In the members of the first group, the fats, one molecule of glycerol is combined with three of fatty acid: oleic acid $C_{18}H_{34}O_2$, stearic acid $C_{18}H_{36}O_2$, and palmitic acid $C_{16}H_{32}O_2$, are the three which account for the bulk of the fatty acids of the neutral fat fraction of body tissues. The latter two are saturated, while oleic acid has a double bond in the middle of its fatty acid chain. This renders it less stable and more easily oxidized. Oleic acid is liquid at low temperatures while stearic and palmitic are solid even at body temperature. It is now thought that the glycerides are usually mixed, i.e., they contain two or more different fatty acids in their molecule. Fatty acids more unsaturated than oleic (linoleic and arachidonic) are also found in the triglycerides.

The neutral fats obtained from animal tissues contain fatty acids which have an even number of carbon atoms. The characteristic fatty acids in the depôt fat vary with different animals. Hilditch and Lovern have shown that certain fatty acid mixtures are characteristic of marine animals, others of fresh water fish and others for land animals. The fat of the fish, for example, contains large quantities of higher unsaturated fatty acids C_{20} and C_{22} , but in the depôts of ox and pig these are almost absent.

DISTRIBUTION. Reserve fat is found in the so-called interstitial tissue of all organs with the exception of the brain. There may be very large masses of this material in subcutaneous tissue and in various other places such as in the omentum, the perirenal fat depôt and so on. (See table 56.)

The distribution of fat has been found to be independent of the type of diet which, however, controls the amount and in many species the character of the fat deposited.

PHYSIOLOGY. The main function of the glycerides is undoubtedly to provide a source of energy.

¹ The phospholipids, cerebrosides and waxes which resemble fats may be termed lipoids or fat-like substances. The sterols and hydrocarbons while associated with fats are chemically quite distinct.

Fat not only furnishes more energy per gram (9.3 calories) than carbohydrate and protein but it is the only food material stored in the dry state. The total fat content of a well-nourished animal may be between 10 and 12 per cent and under unusual conditions much higher. A very large proportion of the total energy store of the body is in the form of fat.

While animals grow normally when diets containing only very small amounts of fat are provided, several investigators have reported that growth is seriously retarded on a diet free of fat (McAmis, Anderson and Mendel). Palmitic, stearic and oleic acids are not essential but Burr and Burr have provided evidence that certain of the unsaturated fatty acids are necessary. Growth is favorably affected by linoleic, linolenic and arachidonic acids and the development of skin

no difference in saturation of the fat from the superficial subcutaneous region and that of deep and warmer parts of the body. These latter workers used animals which are not normally subjected to extremely low temperatures.

Recovery from the depôt fat of a particular dietary fatty acid, has been repeatedly demonstrated. This deposition is, however, limited to the higher fatty acids (above C₁₀). Those of lower molecular weight are apparently called upon first for the provision of energy but they may be built up into longer chains and stored. Thus low molecular weight fatty acids may affect body composition. Schoenheimer and Rittenberg have shown that a portion of stearic acid (labelled with deuterium) may be desaturated to oleic acid and another degraded to palmitic acid. Unsaturated bonds may be hydrogenated and palmitic acid, for example, may be converted to others of shorter or longer length of carbon chains. Interconversion of the fatty acids within the body is thus well established.

lesions (similar to acrodynia) is prevented. These acids should be considered separately in dietary studies since there are definite differences in the magnitude of their effects on growth and on the skin lesions. There is an interesting interrelationship of the actions of the unsaturated fatty acids and those of pyridoxin, pantothenic acid and other accessory food factors.

In some species, of course, the layers of fat in the subcutaneous spaces serve as an insulating mechanism against extreme cold. Thus in cold climates the fat deposited just under the skin contains a relatively large amount of oleic acid. It is therefore more liquid than the material which is found in the less superficial subcutaneous reserves. Henriques and Hanson have pointed out the fact that since the temperature of the outermost subcutaneous fat is appreciably lower than that of the deeper parts, the body requires a more easily mobilizable type of fat at this place. In a somewhat similar investigation of fat in different parts of the body Anderson and Mendel could find

Conversion of carbohydrate and protein to fat

The formation of body fat from carbohydrate of the diet was established by the classical work of Liebig (1852) and Lawes and Gilbert (1853). The rate at which the fatty acids are formed has now been studied by the use of deuterium. Schoenheimer and his colleagues found that palmitic and stearic were made at the same rate but that the formation of the unsaturated acids was slower. The body is able to introduce one double bond but not two and the highly unsaturated fatty acids (such as linoleic and linolenic) are therefore not found in this "synthetic" fat.

The formation of carbohydrate from protein is well established. It has been assumed that this newly formed carbohydrate is available for fat synthesis and good evidence for this assumption has been added recently by Longenecker and by Hoagland and Snider. On an almost exclusively protein diet the fat formed was similar in composition to that synthesized from dietary carbohydrate.

Many of these recent additions to our knowledge establish the fact that the fat depôts are not essentially inert storehouses of energy as was previously thought, but are centers of continuous metabolic activity.

The phospholipids

CHEMICAL STRUCTURE. The phospholipids may be divided into the monoamino-monophospho-

lipids in which the ratio of nitrogen to phosphorus is 1:1 and the diamino-monophospholipids in which the ratio of nitrogen to phosphorus is 2:1. The monoamino-monophospholipids are lecithin and cephalin and perhaps others that have not yet been identified.

* May be esterified with fatty acid.

The lecithins and cephalins are composed of glycerol and fatty acids as are the triglycerides, but one fatty acid may be considered to be replaced by the phosphoric acid-nitrogenous base complex. The base is choline in the case of lecithin and amino-ethanol in cephalin. Another cephalin has recently been isolated (Folch and Schneider) which contains the amino acid serine and this may provide another source of amino-ethanol. Folch and Woolley have found a cephalin fraction in *brain* and *spinal cord* which contains inositol. There is usually one saturated and one unsaturated fatty acid but in some cases two saturated or two unsaturated fatty acids may occur. Oleic and either palmitic or stearic acid are commonly found but more highly unsaturated fatty acids such as linoleic and linolenic have been identified. Sphingomyelin is a diamino-monophospholipid and contains two bases choline and sphingosine and one fatty acid radical but no glycerol is present. Different sphingomyelins containing respectively stearic, lignoceric and nervonic acids have been found.

DISTRIBUTION. The phospholipids, lecithin, cephalin and sphingomyelin are widely distributed in the body and it is thought that all cells contain one or more of these compounds. Sphingomyelin is present in much larger amounts in the brain and nerve tissues than elsewhere and is usually associated with the cerebrosides.

The cephalin content of the brain is considerably higher than the lecithin concentration. In the liver and spleen they occur in almost equal amounts while in the kidney, heart and lung, lecithin predominates in a proportion of about two to one. Cephalin and lecithin have been isolated from the gastric mucosa of pigs but sphingomyelin could not be demonstrated.

The evidence of the French workers Mayer and Schaeffer, and Terroine showed that the amount of phospholipid in a particular organ in a given species remains relatively constant under a variety of conditions including extreme starvation. As a result, they have called this fraction the "élément constant". While this evidence strongly suggests that the lipids are structural components of the cell there are many new findings which emphasize their rapid rate of turnover and their importance in metabolic processes. In table 57 the phospholipid content of various human tissues is given.

PHYSIOLOGY. As emphasized above the phospholipid content of the various tissues is much more constant than that of the neutral fat. How-

ever, this relative constancy must not be taken as evidence of phospholipid inactivity.

There are, however, significant variations in phospholipid due to the amount and character of the diet. The amount in muscle may decrease during fasting while that in the liver increases in some species. The body is able to synthesize the phospholipids if the constituents are available.

Various hormones affect the phospholipid values. Insulin decreases the plasma phospholipid. Repeated injections of thyroid substance increase the amount in liver while removal of the thyroid causes a decrease. With the onset of pregnancy in the human subject the plasma phospholipids show a rise which continues to term (the other

lipids also increase). The work of Aten and Hevesy indicates that milk phospholipids are synthesized in the mammary gland.

Bloor has suggested that the phospholipid content of a tissue may be considered an index of the extent and variety of its physiological functions. Thus, the phospholipid content is increased with physiological activity and decreased when the cells become less active. A secreting salivary gland of the dog (Cambridge, Mayer and Valler) has a higher phospholipid content than the resting one on the other side. The development of the corpus luteum is accompanied by a very significant increase in its phospholipid content (Bloor, Okey and Corner). When the body temperature of rabbits and dogs was greatly reduced by immersion in very cold water, Mayer and Schaeffer found a decrease in the phospholipid content of the liver and a compensatory rise when the animal had recovered from the experience. The phospholipid content of rapidly growing malignant tumor cells

is higher than in normal tissue or in benign of the same tissue.

The relative constancy of the phospholipid content of most of the tissues, the antipathetic physico-chemical effects of cholesterol and phospholipids (Degkwitz) and the aversion of the phospholipids of certain tissues to be oxidized which the phospholipids of certain tissues and retain the highly unsaturated fatty acids support the view that these substances have functions other than to transport fat or to serve as intermediaries in fat metabolism in other ways. Sinclair has stressed the possibility that the phospholipids may act as agents for the transport of fatty acids within the cell. Oxygen may be taken up by the unsaturated bonds in their molecules and in different circumstances released again. If the greater solubility of the phospholipids in fluids, the high degree of unsaturation of the fatty acids (see p. 595) and the change in the level of the phospholipid content of blood as well as with the intensity of fat metabolism focus attention on their possible rôle as intermediaries. An interesting new chapter in the story of phospholipids has been built up around the physiological significance of choline, betaine, methionine, inositol as lipotropic factors. This will be discussed under "The Liver and Fat Metabolism" (p. 601).

The metabolic function of the phospholipids is most readily studied experimentally. The introduction of labelled atoms or groups into phospholipids so that the transportation and conversion into other substances can be followed in the organism has greatly increased the knowledge of the function of these substances. The use of active phosphorus P^{32} (Artom; Chalkoff; Sternum, introduced into fatty acids in place of hydrogen (Schoenheimer) and elaidic acid, the trans isomer of oleic acid which is indistinguishable from a natural fat but does not lose its label during metabolism (Sinclair) have been used in much of this work.

If, for example, the elaidic acid fed is converted into phospholipid as a preliminary step before combustion, then the fatty acid should appear in the phospholipids. If the phospholipids are involved as intermediaries in fatty acid metabolism they must undergo a rapid turnover, new molecules being synthesized to replace those lost by oxidation or diffusion.¹ Thus the rate of turnover

¹ Schoenheimer and Rittenberg (Proc. Roy. Soc. London, **1940**) have suggested the term "regeneration" place "turnover".

ity acids in the tissue phospholipids can be followed by the administration of labelled fatty acids. The turnover of the phosphoric acid is linked both to glycerol and the nitrogenous base measured by radioactive phosphorus.

By these methods it has been shown that the turnover of both the fatty acids and the phosphoric acid is most rapid in the mucosa of the intestine (during fat absorption) somewhat slower in the liver and much slower in the muscles and nerves. Several workers have determined rates of turnover of the lecithins, cephalins and sphingomyelins. Chargaff has stated that 24 hours after the administration of P^{32} more labelled phospholipid than cephalin is found in rat liver and intestine. Hevesy and Hahn found that in the liver the 4th hour the percentage turnover of the phospholipids is the same as that of the lecithins and sphingomyelins. By the 12th hour the percentage turnover of the phospholipids is the same as that of the lecithins and sphingomyelins. These latter investigators postulated the existence in tissues of two cephalins, one "fast" and the other with a "slow" turnover. The turnover of the sphingomyelins in liver is approximately the same as that of lecithin but in the brain the turnover is more rapid than either lecithins or cephalins.

In the brain the incorporation of P^{32} is a slow process and its loss from the brain occurs slowly. The turnover of the cephalins and sphingomyelins is slower than that of the lecithins. The rapid turnover of both the cephalins and lecithins in the liver suggests that they are intermediaries in fat metabolism.

The incorporation of administered P^{32} into plasma phospholipids is a much slower process in cor-

puscles than in plasma. In the hepatectomized dog 6 hours after the injection of P^{32} no radio-active phospholipid could be recovered in the plasma. This observation suggested that the liver is the main site (if not the only one) for phosphorylation of plasma phospholipids.

The cerebroside (glycolipids)

In the cerebroside the base sphingosine is combined with galactose or glucose and a fatty acid. Among these are phrenosin (cerebron) containing phrenosinic acid $C_{25}H_{49}O_6$ and keratin containing lignoceric acid $C_{24}H_{49}O_2$. Two other cerebroside have been reported—nervone which contains nervonic acid and hydroxynervone containing hydroxynervonic acid. The cerebroside, which differ from one another in the nature of the fatty acids or carbohydrate, can be distinguished from the phospholipids by the absence of the phosphoric acid group. They are found particularly in nervous tissue and only in minute amounts elsewhere in the normal body. Their physiological significance is unknown.

The sterols

CHEMICAL STRUCTURE. Cholesterol is the name applied to one of a group of sterols which are found in animal tissues. There are several sterols which differ from each other and which can be separated by fractional distillation. These sterols are complex hydroaromatic secondary alcohols. Cholesterol contains an unsaturated carbon atom and its formula as slightly modified by Windaus and Heilbron, Simpson and Spring, from that suggested by Rosenheim and King, is shown in the following figure.

DISTRIBUTION OF CHOLESTEROL. Cholesterol is an essential constituent of all cells and fluids of the body. It exists in the free state and also combined with fatty acids as esters. These two forms are not equally distributed. In bile it occurs only in the free state and tends to vary with the amount in blood. In the corpuscles of human blood, cholesterol exists chiefly in the free state, while in the plasma more than half is present as the ester.

The free cholesterol content of tissue is characteristic and normally remains almost constant

TABLE 58

while the esters are subject to considerable variation in amount. The brain and suprarenals have the richest supply. In the former it is found mainly in the free form. (See table 58.)

In human liver the total cholesterol is about 0.24 per cent and in spleen 0.36 per cent (J. A. Gardner).

Table 59 shows the average total cholesterol content of the normal tissues of the rabbit.

ABSORPTION, TRANSPORT AND EXCRETION OF CHOLESTEROL. Cholesterol administered orally is absorbed in only small amounts unless some fatty material is also present in the intestine. Bile and pancreatic juice are said to aid in its absorption. Combination with the bile acids increases the solu-

bility of cholesterol in intestinal fluids. Cholesterol esters are hydrolyzed by pancreatic and intestinal enzymes. These esters are resynthesized reaching the lymph stream which is the main way by which cholesterol is absorbed. Some cholesterol is absorbed directly into the blood stream. It is very interesting that closely related sterols (ergosterol, coprosterol) are absorbed only in very small amounts (Schoenheimer and Sperry). The small intestine contains an enzyme which will split the ester, presumably, under other conditions, will synthesize (Shope; Sperry and Schoenheimer). Part of the absorbed free cholesterol but no cholesterol ester is excreted in the bile and part is changed to coprosterol by hydrogenation and eliminated in the feces. Some unchanged cholesterol is also excreted. The cholesterol plus coprosterol in the feces is usually greater than the cholesterol of the diet. Some of the biliary cholesterol is absorbed in the small intestine. Gardner and Gainsborough state that cholesterol can be found in normal urine and that the amount is increased by cholesterol feeding and in certain diseases. Under these circumstances cholesterol deposits may be found in the kidney tubules.

THE PHYSIOLOGICAL SIGNIFICANCE OF CHOLESTEROL. While there are numerous examples of the physico-chemical antagonism of cholesterol and lecithin very little can be said about the physiological importance of this relationship in the mammal. The interesting structure of the sterol molecule and the relationship to vitamins has been discussed elsewhere. The relationship of the sterols to the carcinogenic materials, hormones, the bile acids, the cardiac glucosides and possibly also to the so-called "organizer" in embryonic tissues provides fascinating material for speculation and stimulus for further work. Indeed, the probability that the bile acids, oestrogens, the corpus luteum hormone and the sex hormone may be prepared from cholesterol in the laboratory suggests that cholesterol may be the "mother substance" of these physiologically important compounds. If this is accomplished, cholesterol will be immediately invested with great physiological importance.

The increased cholesterol of the blood due to fat absorption is probably due in large part to the absorption of cholesterol contained in the pancreatic and intestinal juices and the bile. An increase in cholesterol ester has been taken to indicate that the sterol may play a part in the transport of fatty acids. The increase in cholesterol

ster in certain degenerative conditions of the has been referred to previously. The only by which atherosclerosis can be produced by dietary means is by feeding diets high cholesterol.² Feeding cholesterol is one of the certain means of producing excessive deposition of neutral fat in liver. Under these instances there is also a large accumulation of sterol esters. The increased amounts of sterol esters in liver when cholesterol is fed be a protective reaction and indicate that the is a less harmful form than the free cholesterol. The fatty liver produced by cholesterol is not so readily affected by lipotropic substances as deposition of fat produced by less measures.

The antilipotropic action of cholesterol, is in part at least, by a depression of the rate of phospholipid turnover in the liver. The effects of the various lipotropic factors on the rate of cholesterol esters in the liver is still studied, but choline and methionine appear to be more active than inositol.

It is thought that cholesterol is one of the constituents of bile which makes this substance so important in the emulsification of fats and therefore in their digestion and absorption. There is evidence that cholesterol can be synthesized in the liver since it may be excreted even when very little is obtained in the diet in mammals. Furthermore, it is present in the eggs of birds when the yolk contains little or none of the substance. There is an increase in blood cholesterol during pregnancy. It will be apparent from these remarks that there is a great deal to be learned concerning the physiological significance of the sterols.

THE ABSORPTION OF FAT

(See also p. 462)

The processes underlying the absorption of fat have long been a subject for debate and many aspects of the problem still remain obscure. It is now to be established that, except for small quantities which may be absorbed as a fine emulsion of unsplit fat, hydrolysis of the fat into constituent fatty acids and glycerine is a necessary preliminary to absorption. The possibility that small quantities of fat are transferred across the intestinal mucosa unchanged is suggested by the observation that paraffin oil (which of course is not digested) undergoes some slight absorption

in rabbits and guinea-pigs are the only animals in which atherosclerosis has been produced by this means.

(Channon and Collison). Lanolin, on the other hand, though it is well emulsified, is not absorbed. The view widely held some years ago, that fatty acids are absorbed in the form of soaps, is untenable, for any soaps which might be formed could not be held in solution in the acid fluids of the intestine. Verzár and his colleagues have been led to believe from their experiments that fatty acids form a complex with the bile salts (1 molecule of fatty acid to 3 of bile acid) which is water-soluble and readily diffusible. This power of bile salts to bring water-insoluble materials into solution in the intestinal juices is spoken of as their *hydrotropic action*. According to this conception the bile salt-fatty acid complex diffuses into the epithelial cells. After transference across the epithelial boundary it breaks down into its components, the fatty acid combines with glycerine which has diffused into the cell from the intestinal lumen while the bile salt is returned to the liver in the portal blood stream⁴ (p. 458). There is evidence that an intermediate stage in the resynthesis of the neutral fat is the formation of a "specific" phospholipid. Sinclair found that during fat absorption a change occurred in the composition (but not in the total quantity) of phospholipid in the intestinal mucosa. During fat absorption the fatty acids of this "specific" phospholipid are those of the food fat. After fat with a high iodine number (i.e., a highly unsaturated, e.g., cod-liver oil) has been fed, the phospholipid of the mucosa has a high iodine value also. The belief that phosphorylation of the fatty acid occurs as a step in the synthesis of neutral fat in the intestinal mucosa has been supported by Verzár, but serious doubt has now been cast on his evidence.

Pathway of absorption. Part of absorbed fat can be collected from the thoracic duct lymph. Several investigators have reported that some fat is absorbed directly into the portal system but this is still a very controversial point. Satisfactory data accounting for all the fat which disappears from the intestine have not yet been presented.

The mode of transfer of the neutral fat from the epithelial cells to the central lacteals also remains a matter for conjecture. The leucocytes have been credited with this function but most of the evidence is against their playing such a rôle (see Leach). During fat absorption the central lacteals show rhythmic contractions which evidently serve to

⁴There is recent evidence that some absorption of fatty acids may take place without the participation of the bile salts.

pump the chyle contained within them into the lymphatics tributary to the thoracic duct. Thus the absorbed fat is constantly propelled along the lymphatic channels of the mesentery. By dark ground illumination under the high power of the microscope, the absorbed fat can be observed in the blood as minute particles (less than 1μ in diameter) termed *chylomicrons* (fig. 236).

Fat is not only transported as chylomicrons but as phospholipids, cholesterol esters, and possibly as lipoproteins. The relative importance of these mechanisms is a subject for further research.

THE ELIMINATION OF FAT FROM THE BODY

There is no fat or phospholipid in the urine under normal conditions but the latter may appear in disease. There are only traces of fat in the secretion of the skin.

The fat content of the feces is normally between 6 and 12 per cent of the fat which is absorbed but as Sperry has pointed out this bears no relation to the foot fat. In dogs, even after five weeks or more on a fat-free diet, there are considerable amounts of fat in the feces. Some 60 per cent of this is neutral fat and 40 per cent fatty acids. A large part of this lipid excretion is composed of bacteria and cellular debris.

When the bile duct is ligated, large, light colored stools are usually observed as this procedure interferes greatly with fat absorption. Digestion is nearly complete, however, as is shown by the fact that the fat is excreted chiefly as fatty acids. Fatty stools are found also when the pancreatic ducts are tied although the absorption of fat is by no means completely prevented. When pancreatic lipase is excluded in this way the fat is excreted as glyceride rather than as fatty acids.

BLOOD FAT

An analysis of the fatty materials occurring in the plasma of human subjects has been made by Boyd. His results are given in table 60. The amount of these materials occurring in the plasma of animals in the post-absorptive state does not vary greatly under normal conditions. If, however, a sample of blood is withdrawn four to six hours after the ingestion of a large amount of fat such as olive oil or thick cream, a distinct milkiness of the plasma may be observed. This is due to the presence of the tiny microscopic fat particles—chylomicrons (fig. 236) which have been mentioned previously. The extent to which the amount of fat in the blood has increased may be determined

by counting these particles under a dark field microscope as well as by the chemical methods already described for other tissues. Such a alimentary lipemia, as it is called, has been observed both in man and in animals, although does not occur in all species. Great variations in the magnitude of the increase may be observed in a single individual under apparently identical experimental conditions. This is not surprising when we consider that the amount of fat present in the blood at any given instant will depend on the balance between the rate of absorption from the small intestine on one hand and the rate at which it is being utilized or laid down as adipose tissue on the other. The rate of absorption from the intestine will depend on such factors as the emptying time of the stomach and the degree of emulsification. The factors which determine whether

fat is utilized or laid down as adipose tissue are as yet unknown. It is obvious, therefore, that the degree of alimentary lipemia cannot be used simply as an index of the rate at which fat is being absorbed. Although the increase in blood lipids which we have been discussing is due chiefly to neutral fat, changes in the other fractions have been observed also during fat absorption. The phospholipids as a rule show a small and somewhat irregular rise, the significance of which will become clearer when further work on labelled molecules has been completed.⁵ The changes in cholesterol are even more irregular, and may be due solely to cholesterol which is poured into the intestine when fat is being absorbed. It is possible that changes in cholesterol from the free to the esterified form may be of some significance, but at present there is no direct evidence for the participation of cholesterol in the early stages of fat metabolism.

⁵ The phospholipids of the plasma are, in large part, those which contain choline and their rate of turnover is increased by feeding choline (Chaikoff).

THE LIVER AND FAT METABOLISM

The main facts which indicate that liver plays a particularly important part in the metabolism of fat are the following: (1) the fatty acids combined as liver phospholipids and glycerides are more unsaturated than fatty acids found in other tissues. (2) Under a great variety of conditions neutral fat or cholesterol esters may accumulate in the liver to a very much greater extent than in any other tissue. (3) The liver is the principal if not the only site of formation of the ketone bodies. (4) The rate of phospholipid turnover in the liver is more rapid than in any other tissue, with the possible exception of the intestinal mucosa during fat absorption.

FIG. 236. Shows chylomicrons. (After Gage.)

(1) The fact that the phospholipid fatty acids of the liver are more unsaturated than those in other tissues suggests either that double bonds have been introduced into the fatty acid molecule in the liver (Leathes and Meyer-Wedell) or that the liver cells selectively retain the more unsaturated fatty acids (Raper). Using fatty acids "ear-marked" with deuterium, direct evidence of the desaturation of these acids in the body has recently been secured by Schoenheimer and Rittenberg, but further work is required to determine the rôle of the liver in this process.

(2) The various conditions which result in an excess of fat in the liver may be classified as follows:

1. Dietetic means—starvation, the feeding of diets rich in fat, or cholesterol, diets deficient

in choline, methionine, or other lipotropic factors.

2. Injection of substances obtained from the anterior pituitary gland.
3. Pregnancy, pernicious anemia, and diabetes.
4. Changes in atmospheric conditions—high and low temperature, low pressure.
5. Infectious processes.
6. Poisons—phosphorus, chloroform, benzol, phloridzin, etc.

The amount of fat which is present in the liver at any time depends on the following factors:

1. The rate at which fat is brought to the liver by the blood.
2. The rate at which the liver is able to take up fat from the blood.
3. The rate at which the liver can deal with fat, (a) by direct oxidation in the liver cells, (b) by passing it on in the same or in a slightly changed form to other parts of the body.
4. The possibility that fat may be synthesized in the liver from other materials.

There is an increase in the fat of the liver within a few hours after the ingestion of a meal containing large amounts of fat. Under these conditions the fatty acids of the liver glycerides and lipids are affected by those in the diet. Under other conditions when no fat is fed the liver may become intensely fatty, and here the fatty acids are derived from the depôt fat from ingested carbohydrate or protein. When "ear-marked" fats are deposited in the tissues and then some poison such as phosphorus or chloroform is administered the excess of liver fat contains the fatty acids which were present in the depôt fat. Cholesterol feeding causes a deposition of glyceride and cholesterol esters in the liver (Yuasa; Chanutin; Okey).

CHOLINE AND OTHER LIPOTROPIC⁶ FACTORS IN

FAT METABOLISM. Choline ($((\text{CH}_3)_3\text{N}-\text{CH}_2\text{CH}_2-\text{OH})$ which was first isolated from body fluid (bile) by Strecker in 1849 has long been known as a

⁶ The term lipotropic was originally used to describe the action of choline which prevented the deposition of, or accelerated the rate of removal of fat from the liver. It now has a somewhat broader meaning and is used to describe the action of other substances with a similar action on fat metabolism. Substances such as cholesterol which cause a deposition of liver fat are referred to as antilipotropic and diets free of lipotropic factors may be described as alipotropic. Cystine, under certain dietary conditions increases the deposition of liver fat and the incidence of hemorrhagic kidneys. This is apparently related to a stimulation of metabolism ather than to a direct antilipotropic effect.

component of lecithin and sphingomyelin. Its acetyl derivative, acetylcholine, has assumed a position of great physiological importance since the work of Lowei, Dale and others as discussed elsewhere. Choline, itself, has now been shown to be an important dietary factor, which exerts a profound effect on the storage and transport of fat in the animal body, on growth, and on various other physiological mechanisms.

In 1924 Allan, Bowie, Macleod and Robinson, and Fisher noted large fatty livers in insulin treated depancreatized dogs. This fatty change was prevented when raw beef pancreas was included in the diet. Hershey and Soskin noted a similar effect with crude egg lecithin and in studies on the fatty livers produced by dietary means in rats, Best, Hershey and Huntsman later identified the active component of lecithin as choline. This finding led to a long series of studies on the significance of choline as a dietary factor. Betaine and casein were found to exert effects similar to choline on the mobilization of fat (Best and Huntsman). Other proteins have since been found to be lipotropically active. The activity of casein is due in large part to its methionine content (Tucker and Eckstein). Methionine exerts its lipotropic action by transferring its methyl group to ethanolamine with the formation of choline (du Vigneaud; Stetten). Betaine also acts as a methyl donor (Stetten).

When these lipotropic factors are not available in the diet large amounts of fat accumulate in the liver. In young animals hemorrhagic lesions are seen in the kidneys and other tissues (Griffith and Wade), and these may produce death. The antilipotropic⁷ factor cholesterol aggravates the liver and kidney changes while choline, betaine and methionine prevent their development.

In depancreatized or normal dogs dietary conditions which permit fat to accumulate in the liver result eventually in cirrhosis of this organ (Chaikoff). In rats a hypolipotropic diet produces both necrosis and cirrhosis. These lesions which have been studied particularly by György and Goldblatt, Blumberg and McCollum, and Daft, Sebrell and Lillie, may be interrelated. Sebrell et al. have supplied evidence that choline prevents the cirrhosis; cystine, in small amounts, prevents the necrosis; and methionine which aids in the formation of choline in the body and also like cystine supplies sulphur, prevents both necrosis and cirrhosis. Furthermore, the acute effects of

chloroform poisoning on the liver in protein depleted dogs are diminished or prevented by the administration of methionine or choline plus cystine (Miller and Whipple).

The lipotropic action of choline has been studied by labelling the molecule with arsenic (Welch), radioactive phosphorus (in the lecithin) (Perlman and Chaikoff) and heavy nitrogen (Stetten). The results of all these studies indicate that choline accelerates the rate of phospholipid turnover in liver and kidney and to a lesser extent in other tissues.

In the depancreatized dog choline has been shown to be one of the active components of beef pancreas which as previously stated prevents the development of fatty livers. The protein of pancreas through its methionine content will presumably also exert a lipotropic effect. Furthermore, the pancreatic enzymes will help to liberate choline and methionine from the phospholipids and protein of the diet. Dragstedt and his colleagues have shown, however, that certain pancreatic extracts contain active materials other than choline and protein. It has been suggested by McHenry and Gavin that one of these may be inositol, which they have shown to be lipotropic in rats under certain conditions. Dragstedt and his colleagues find that inositol may exert a slight effect. They believe, however, that the pancreas contains another unidentified factor which affects the deposition of liver fat in depancreatized dogs. This view is also held by Montgomery, Entenman, Gibbs and Chaikoff, but they feel that the unidentified lipotropic factor is not the pancreatic hormone "lipocaic" postulated by Dragstedt.

FAT AND GLYCOGEN IN LIVER. While it is true that very small amounts of glycogen are present in very fatty livers and that the fat content is low when large amounts of glycogen are found, it can also be shown that moderate amounts of glycogen can accumulate in moderately fatty livers.

THE LIVER AND THE FORMATION OF KETONE BODIES. The main points of evidence that the ketone bodies are produced in the liver are as follows: (1) It was shown by Embden and Kalberlah that a liver perfused with long chain fatty acids with an even number of carbon atoms produced acetone. (2) Using the liver slice technique in the Warburg apparatus, Quastel and Wheatley showed that fatty acids with an even number of carbon atoms are broken down to the ketone bodies. (3) In a depancreatized dog showing a profound ketosis the ketone bodies in the blood

⁷ See footnote to page 601.

rapidly diminish after removal of the liver (Chaikoff and Soskin). (4) The rapid rise in the ketone body content of rabbit's blood produced when certain extracts of the anterior pituitary are injected is not observed after hepatectomy (Mirsky). (5) Substances which damage the liver frequently decrease ketosis.

OXIDATION OF FAT AND THE FORMATION OF KETONE BODIES. Although fatty acids are resistant to ordinary chemical oxidizing reagents, they are broken down completely to carbon dioxide and water in the body with the utmost facility.

acid molecules formed by this β -oxidation were rapidly broken down to carbon dioxide and water. Knoop's work was confirmed by Dakin who also studied the *in vitro* oxidation of the various fatty acids by H_2O_2 at body temperature. This data supported the theory of β -oxidation. Embden and his colleagues perfused various fatty acids through isolated livers and found that ketones were formed only from fatty acids with an even number of carbon atoms in the molecule. These findings taken together appeared to indicate that the last four carbon atoms in the fatty acid chain, under-

FIG. 237. Section from liver of depancreatized dog fed a diet low in choline. Ether-soluble material over 60 per cent of wet weight. $\times 200$. (From Best, Huntsman and Young.)

This made the detection of intermediate products extremely difficult and has been one reason for the slow progress of research in this field. The theory of successive β -oxidation which originated from the work of Knoop (1905) has occupied an extremely prominent position in the considerations of this subject. Knoop fed various phenyl substituted fatty acids to his test animals and identified the excretion products in the urine. The results were explained by assuming that the fatty acids were broken down by the splitting off of two carbon atoms at a time, i.e., by oxidation at the carbon atom which occupies the β -position to the carboxyl group. It was assumed that the acetic

went oxidation at the β -position but were not further degraded. Thus it was assumed that irrespective of the length of chain each even numbered fatty acid gave rise to one molecule of ketone.

In 1916 Hurtley tried to find the butyric and acetic acids which would be expected to be formed in the liver during active ketone formation. He was unable to find any trace of these acids. Several groups of workers who repeated the *in vitro* work of Dakin found that while β -oxidation did occur the oxygen could also become attached to the α and γ positions. In 1935 and 1936 Deuel and his collaborators found that more ketone bodies were formed in an animal fed octanoic acid than in one

given an equimolar amount of butyric acid. Jowett and Quastel, 1935, and Leloir and Muñoz, 1939, reported that the amount of ketone bodies formed by liver slices could not be accounted for on the assumption that only the last four carbon atoms of these fatty acids give rise to a ketone body as the theory of β -oxidation demanded. Blixenkrone-Møller, 1938, and Stadie, Zapp and Lukens, 1940 and 1941, studying perfused livers and liver slices *in vitro*, found that the oxygen consumption was far smaller than would be the case if all but the last four carbon atoms of each fatty acid were being broken down to acetic acid and this acid oxidized. The very important new fact had been established by the work of Jowett and Quastel, 1935; Edson, 1936; and Leloir and Muñoz, 1939, who worked on isolated tissues, and by MacKay, Wick and Barnum, 1940, who used intact animals. These investigators agree that the odd numbered fatty acids also give rise to smaller but significant amounts of the ketone bodies. Thus the theory of β -oxidation is not adequate to explain all the facts.

In 1916 Hurlley proposed the theory of multiple alternate oxidation to account for his failure to find butyric acids in livers where ketone formation was actively progressing. This theory required that the intact fatty acid chain be first oxidized at each alternate carbon atom and then split into blocks of four carbon atoms each. One molecule of palmitic acid $C_{16}H_{32}O_2$ would give rise to four molecules of aceto acetic acid.

Many workers, Jowett and Quastel, Brentano and Markees, Deuel and his collaborators, have found that fatty acids such as caprylic, capric or lauric acids would form more ketone bodies than either butyric or caproic acids in liver slices or in intact animals. The latter series possesses shorter carbon chains than the former. Blixenkrone-Møller, working with isolated liver of cats, reported that the fatty acids must be broken down to four carbon acids to explain the low oxygen to ketone body ratio which was observed. Stadie, Zapp and Lukens found that the mean value for the molecular ratio of oxygen uptake to the ketone body formation was very close to the value which could be expected if the average fatty acid $C_{16}H_{32}O_2$ was broken down to four molecules of aceto acetic acid. These authors also showed that the ratio of ketone body increase to that of fatty acid decrease, was very close to four.

The multiple alternate oxidation theory, however, implies a phenomenon which is rather

difficult to explain upon biochemical grounds. It is possible that the simultaneous oxidation of every alternate carbon atom in the fatty acid can take place but there is no reason why the molecule should be selectively split at every second keto group instead of at every one. Furthermore it was observed that odd-numbered fatty acids such as valeric acid $C_5H_{10}O_2$ could produce small amounts of ketone bodies when added to liver slices (Jowett and Quastel). It is known also that valeric acid can give rise to glucose through propionic acid and when this happens the two carbon atom fragment is left over. In order to explain why valeric acid can bring about the formation of ketone bodies it must be assumed that two of the acetic acid molecules condense to form acetoacetic acid. MacKay and his colleagues have conducted feeding experiments in intact animals which lend support to this interpretation. They have postulated a modification of the previously mentioned theories which they have named the " β -oxidation acetic acid condensation hypothesis". When propionic acid was fed to animals liver glycogen accumulated without the formation of ketone bodies. Valeric acid on the other hand led to both glycogen formation and the production of ketone bodies. According to MacKay's theory all fatty acids, whether they possess an odd or even number of carbon atoms, are oxidized at each alternate carbon atom. The molecule then splits at every keto group to form acetic acid molecules except where a three-carbon chain remains as propionic acid. This latter residue could be converted to carbohydrate via either lactic acid or succinic acid. It has been shown that acetic acid can condense to form ketone bodies, (Friedmann, 1913). The hypothesis of MacKay, Wick and Barnum, 1940 offers the most satisfactory explanation for the facts as we now know them.

INTERRELATIONSHIP OF THE KETONE BODIES
It is now believed that acetoacetic is the first of the ketone bodies to be formed. This acid may be reduced to β -hydroxybutyric in various mammalian tissues and the reverse process also takes place. Acetone is formed readily in biological fluids containing acetoacetic acid and this process presumably accounts for its presence.

SOURCE AND SITE OF FORMATION OF KETONE BODIES. Embden, Salomon and Schmidt (1906) found that the ketone bodies were formed in perfused livers when fatty acids, certain amino acids or pyruvic acid were added to the perfusate. This finding has been repeatedly confirmed. Fat, how

and the conditions in which there is an excessive deposition of fat in the liver (p. 601) are discussed elsewhere. A profound disturbance of phospholipid metabolism occurs in Niemann-Pick's disease, a condition which is seen in infancy and in early childhood and is invariably fatal. The spleen and liver are enormously enlarged and contain very large amounts of phospholipids. The cholesterol content of these tissues is also increased but not to nearly the same degree. The blood phospholipid is also definitely raised. Histologically there is a great hypertrophy of the reticulo-endothelial system. Very little is known about this disease but it has been suggested that there is some interference with the activity of the enzymes which are responsible for various stages of fat metabolism in the tissues.

In 1893 Hand described a condition in children which was characterized at autopsy by yellow nodules in the cranial bones and in other situations. Since it will become increasingly difficult to add more names when further cases are described it may be expedient to call the syndrome Hand's disease (Hand-Schuller-

Christian, etc.). While these nodules show a predilection for the tissues of the head, i.e., cranial bones, orbit, tuber cinereum, they have been noted in most portions of the skeleton (Chester and Kugel). The signs and symptoms depend on the areas affected. Diabetes insipidus and exophthalmos are common disturbances, i.e., due to lesions near the pituitary gland and in the orbit. Rowland believes that the condition is due to an osseous form of xanthomatosis. These xanthomatous nodules contain large amounts of cholesterol and cholesterol esters, which together may account for a large proportion of their total fat. There is no alteration in the fat content of the unaffected parts of the body. The etiology of the disease is unknown. The generalized xanthomatosis, which is sometimes seen in diabetes mellitus, may disappear when the blood fats are reduced to normal values by appropriate treatment of the diabetic condition.

There is an increased amount of kersin in the spleen in Gaucher's disease.

A great deal of attention is being paid at the present time to the metabolism of fat in tumor tissue but no review will be attempted here. The important part played by cholesterol in the formation of gall-stones has been dealt with (p. 467).

CHAPTER LII

THE METABOLISM IN STARVATION (FASTING), OBESITY AND UNDERNUTRITION

STARVATION

An animal deprived of food derives energy first from the combustion of its own carbohydrate stores (glycogen). Next, the fat reserves are drawn upon and finally, after these have been exhausted, tissue protein is broken down, the fatty acid part of the molecule is burned while the nitrogen is excreted in the urine as urea. The metabolism of several professional fasters has been investigated. Among the most famous of these are Succi, whose metabolism was studied by Luciani and others, Cette, investigated by Munk and Zuntz, Levanzin by Benedict and Beauté by Cathcart. One of the longest of such fasts upon record is that of Merlatte of Paris which lasted for 50 days. A dog has been starved for 117 days. By the end of this time it had lost 63 per cent of its weight, but was fairly active. Succi on the 40th day of his fast had lost about 25 per cent of his weight. The length of time a man could survive would depend largely upon his physical condition (fat stores, etc.) at the commencement of the fast, but it would probably not exceed 9 or 10 weeks in any event. Terence MacSwiney, Mayor of Cork, after his arrest during the Irish troubles in 1920, went upon a hunger strike which lasted 74 days; it was terminated by his death in coma.

During starvation the loss of weight is not distributed evenly throughout the body, some organs and tissues losing a much greater proportion of their weight than others (fig. 238). During the first few days the subcutaneous tissues and other fat depots bear the brunt of the effect of the fast. Large quantities of extracellular water are also lost at this time. Later, dissolution of muscular tissue occurs, as indicated by the N:S ratio of the urine (about 14:1). The water lost during this period is derived mainly from intracellular sources. Even in prolonged starvation the brain and heart lose a very small proportion (between 3 and 4 per cent) of their weight.

NITROGEN EXCRETION. *The total output of nitrogen* in the urine falls for the first day or two of the fast when the body is subsisting upon its carbohydrate supplies (p. 554). The length of this period varies, of course, with the size of the

carbohydrate stores at the commencement of the fast. A steady rise in nitrogen excretion follows, and usually reaches a maximum about the third or fourth day, but from then on it shows a progressive decline and may reach a value of less than 6 grams per day. The nitrogen excreted during the earlier part of the fast is apparently derived largely from the mobilization of "deposit protein" (p. 546). The *urea nitrogen* excretion at first rises, then falls; its percentage of the total nitrogen excretion also diminishes. The *ammonia* excretion rises. The *creatinine* output shows a steady decline but this is largely compensated for by the appearance of creatine (p. 550) so that the creatinine + creatine excretion remains fairly constant. The total output of nitrogen shows a pronounced rise shortly before death—the so-called *pre-mortal* rise. This probably indicates the exhaustion of the fat stores and the greater utilization of body protein for energy purposes. The total quantity of body protein catabolized may be determined by calculation from the total nitrogen excretion on the assumption that tissue protein contains 16 per cent of nitrogen and that practically all the nitrogen derived from the break-down of body protein appears in the urine. That is, each gram of urinary nitrogen represents the deamination of 6.25 grams of protein, so the quantity of protein broken down is calculated by multiplying the figure for the nitrogen excretion by 6.25. On this basis the average daily loss of body protein of an average sized man during starvation is about 50 grams or about 0.4 per cent of the total amount in his body. For a few days following the termination of a prolonged fast the nitrogen excretion shows a pronounced fall—nitrogen is retained for the reconstruction of tissue protein.¹

PHOSPHORUS AND SULPHUR. The urinary excretion of these elements shows an initial rise, and then a gradual decline, thus showing a curve

¹ The loss of protein varies widely among different organs and tissues. Addis and his colleagues found that in rats fasted for 7 days the several tissues contributed to the total protein loss in the following proportions, muscles and skin 62 per cent, liver 16 per cent, alimentary tract, spleen and pancreas 14 per cent, blood 6 per cent, kidneys 1 per cent, heart 0.5 per cent and the remaining organs 0.5 per cent.

which roughly parallels that of the total nitrogen excretion. Toward the latter part of the fast

the N:P and N:S ratios are around 5.3:1 and 14:1 respectively, i.e., approximately the ratio of these elements in muscular tissue.

The excretions of *chlorine, sodium, potassium* and *calcium* are reduced after the first few days of the fast but the normal levels of these minerals in the blood are maintained and their concentrations are much lower in the urine than in the body fluids and tissues, evidence that they are conserved. In the early days of the fasting period the sodium of the urine exceeds the potassium, indicating that extracellular water is being discharged (p. 18). Later the sodium, potassium and magnesium are in about the same relative concentrations in the urine as in the solid tissues; they are probably derived from the break-down of the latter. The calcium excretion is relatively large, indicating some dissolution of bony structures.

ACIDOSIS. The increase in urinary ammonium (p. 392) is a result of the production of excessive amounts of acid metabolites, especially β -hydroxy

FIG. 238. Diagram showing the relative loss of weight of various organs during starvation as percentages of their initial weights. Contrast the loss of 97 per cent of the weight of body fat with the diminution of only 3 per cent in the weight of the brain; and the loss of 31 per cent of the weight of the skeletal muscles with a loss of only 3 per cent of the weight of the heart. (After Parsons, constructed from Voit's data.)

† Previous day = 661.

butyric and acetoacetic acids. The latter are formed as a result of the carbohydrate deprivation, and the consequent incomplete combustion of fat. Succi toward the end of his fast excreted, daily, from 7 to 13 grams of acetone bodies. In a fasting, very obese, female subject (237 pounds, 4 feet 1 inch tall) reported by Folin and Denis the acidosis was extreme, some 18 grams of β -hydroxybutyric acid being excreted upon the fourth day of the fast.

CARBOHYDRATE METABOLISM. Even in the later stages of the fast glycogen is found in the liver, and the blood sugar is little depressed. Sugar is apparently synthesized from protein. In the earlier stages there may be a temporary hypoglycemia.

The *basal metabolic rate*, the *body temperature*, *pulse rate* and *blood pressure* all show a progressive fall throughout the fasting period. See table 62.

OBESITY

Some forms of obesity are due to a hypothalamic disorder (p. 884); to disease of the pituitary (p. 737, 740) or adrenal cortex (p. 698); or to hypofunction of the gonads. The increase in weight following the menopause, ovariectomy or castration is well known. In other instances obesity may be traced to subnormal thyroid function. These types of obesity are termed *endogenous*. The common type of obesity is usually the result simply of the consumption of a diet possessing a caloric value in excess of the energy requirements of the individual, a part of the excess energy of the food being stored as adipose tissue. The fundamental cause of this type is, therefore, overnutrition. Bluntly expressed, the subject eats too much for the exercise he takes. Obesity of such a type is, therefore, termed *simple*, *exogenous* or *alimentary*.

It must be remembered that the law of the conservation of energy holds for the animal body (p. 523). The energy taken in the food is either expended or stored within the body in the form of carbohydrate, protein or fat. So, whether the obesity is endogenous or exogenous it is due to an energy intake in excess of the expenditure, the balance being stored as fat. In most cases of the endogenous type the metabolism is low, i.e., energy expenditure is reduced, and this, no doubt, is the important factor in the production of the obesity.

SIMPLE OBESITY

In certain cases falling into the class of simple obesity there appears to be a constitutional element and a familial tendency. An inherent inclination to fatness seems to be illustrated by the common observation that of two persons who eat about the same amount of food, and exercise to the same extent, one may remain thin or of normal weight while the other grows fat. Furthermore, the "spare" person may have a large appetite and remain underweight while the obese may diet himself and still be fat. In order to explain such cases it has been suggested that they are due to an inherited endocrine characteristic, i.e., that they are in part at least endogenous in nature. Yet if this were so, some evidence of it should be forthcoming from metabolic studies. On the contrary, the basal metabolic rate per unit of body surface of the subject of the common or simple type of obesity is within normal limits—that is, his energy expenditure at rest is not less than the normal. Nor is work performed more economically than usual by the obese; the reverse is probably true on account of the greater amount of inert adipose tissue. His greater storage of energy cannot therefore be explained upon this basis. It has been claimed that the specific dynamic action of food (p. 554) is reduced in cases of simple obesity; and it has been suggested that such a reduction, by conserving energy, may play a causative rôle. The smaller specific dynamic action which has been observed could, however, account for no more than a 3 per cent reduction in the total daily metabolism, and is quite inadequate as an explanation. An almost inappreciable increase in the caloric intake or a slightly reduced bodily activity would produce a much greater effect upon the energy exchange. For example, 10 grams of extra fat daily in the diet (e.g., a teaspoonful of butter) yielding 90 Calories, or 23 grams of sugar (about 2 teaspoonsful) would increase the caloric intake of a person of ordinary activity by 3 per cent or so, while a slow walk of a mile would increase the metabolism to a corresponding extent.

It is probable that a hereditary or constitutional factor, in the great majority of instances of ordinary obesity, is more apparent than real, and that a careful investigation of these cases with respect to food intake and muscular activity would reveal a positive energy balance. It is therefore likely that, when obesity shows a familial tendency, the inclination of members of

the same family to follow similar habits with respect to diet and exercise, rather than some inherited endocrine peculiarity, is responsible. Or again, traits which lead to obesity—over-indulgence of the appetite, or a distaste for muscular exertion may be inherited. Also, the obese person often, though not a “big eater,” indulges in highly concentrated food. It may, therefore, be said that though endocrine factors cannot be absolutely excluded in all instances of so-called simple obesity no factors other than diet and exercise are definitely known to exert an important influence.

SUMMARY. The fundamental cause of obesity of whatever type is an imbalance between energy intake and energy output.

I. *Endogenous obesity* is due to the lowered metabolism resulting from a disturbance in hypothalamic or endocrine function, e.g., gonads, pituitary or thyroid.

II. *Exogenous or simple obesity* is the result of maladjustments between food and exercise. It has not been demonstrated that a low basal metabolic rate is a factor in reducing the energy expenditure. Work is not performed more economically, nor is the reduction in the specific dynamic action of food an important influence in the production of simple obesity.

THE “COST” OF OBESITY. (1) Owing to the increased weight, muscular exertion places a greater load upon the heart and circulatory system. The incidence of arterial hypertension is relatively high in persons who are overweight. (2) Dissipation of heat by conduction and radiation (p. 623) is reduced through the heat-insulating effect of the mantle of subcutaneous fat. Sweating is in consequence more profuse. (3) Diabetes is more common in the obese than in persons of normal weight. Joslin refers to diabetes as “the fatman’s folly,” and to obesity as “the open door to diabetes.” (4) Persons who are grossly obese are said to be less resistant to infections and poorer surgical risks than those of normal weight. (5) The incidence of gallstones is relatively high in the obese; according to Baumann, 88 per cent of persons with gallstones are overweight. (6) *Life expectancy.* Insurance statistics show that overweight after the age of 35 years is associated with a death rate much higher than that of lean persons or of those of normal weight, a fact which has been pithily expressed in the phrase, “the longer the belt the shorter the life.”

GENERAL PRINCIPLES IN THE TREATMENT OF OBESITY. The basis of treatment should be, as already indicated, (a) reduction in the caloric intake and (b) increase in the energy expenditure through exercise. The dietary restrictions should not be extreme and should be made gradually. The extent to which the caloric intake should be reduced will depend upon the degree of obesity and the amount of exercise prescribed but it should never be pushed to the point where the protein of the subject’s tissues is drawn upon for energy purposes; nitrogen equilibrium should be maintained. Above all things a properly balanced diet should be devised and an adequate supply of vitamins and minerals provided. When the obesity is pronounced (body weight 25 per cent or more above normal), weight reduction is brought about by placing the subject upon a diet possessing a caloric value 40 or even 60 per cent below his energy requirement; he is thus forced to consume his own fat. The caloric value of human adipose tissue is about 3500 Calories per pound.² The total requirement of the average obese subject is around 2500 Calories per day. A reduction in the energy intake by 40 per cent of the requirement, that is, 1500 Calories, will therefore entail a weight loss of nearly a third of a pound per day. The subject is kept upon the restricted diet until the desired weight has been reached; his caloric intake is then adjusted to his requirement (see p. 663).

It is toward the restriction of the more concentrated forms of food that attention is particularly directed. It will be recalled that the caloric value of fat is more than twice that of carbohydrate. Also fatty foods, since they contain little or no water, are more concentrated than starchy materials. Lard, dripping, olive oil, etc., are 100 per cent fat, whereas the protein and carbohydrate of white bread amount together to only about 60 per cent of its fresh weight. Ordinary fats and oils should therefore be restricted. Butter, though about 85 per cent fat, should not be disallowed owing to its value as a source of vitamin A. Sugar in the form of sweetening for beverages, in jams, honey and chocolates is a highly concentrated food. By curtailing its consumption a large reduction in the caloric value of the diet can be effected without the disadvantage attending the reduction of some of the other foods. Bulky foods, e.g., green vegetables and salads of low caloric value but satisfying to the appetite may be substituted. Undue restriction of the water intake is sometimes practised but this measure appears to be of no benefit and may be a detriment to health. Alcohol has a high caloric value and is therefore, except in minimal amounts, excluded from the diet. *Thyroid extract* is sometimes employed to raise the metabolic rate and so reduce the obesity. The hormone is clearly indicated as a means of raising a low metabolic rate to

² Pure human fat has a caloric value of approximately 9.5 Cal. per gram. 3500 Cal. per pound here given is the value after allowance has been made for connective tissue and water content.

normal, otherwise its use is not to be advocated except in exceptional cases and only when the subject's basal metabolic rate can be followed by frequent determinations. *Dinitrophenol* is another agent which raises the metabolic rate and has been employed with success in the treatment of obesity. It is a dangerous drug unless given under the strictest supervision. Cataract has been reported following its use; liver injury may also result.

UNDERNUTRITION (INANITION)

If a diet possessing a caloric value considerably below the energy requirements of the individual is persisted in, as during famine, war blockade, extreme poverty, disease (e.g., stricture of the esophagus or pylorus) or improper feeding of infants, serious nutritional effects result. It must also be remembered that just as an intake of calories over the output will cause obesity so an energy expenditure in excess of the caloric intake will result in a loss of weight. Consequently a man who performs heavy work upon a diet which is adequate only for a sedentary worker will suffer from undernutrition. The economic or other conditions which lead to extreme reductions in the total caloric value of the diet obviously must also cause, as a rule, a reduction in the intake of vitamins, essential minerals and first class proteins. As a consequence, the incidence of specific deficiency disorders, e.g., stunting, xerophthalmia, rickets, osteomalacia, scurvy, etc., is also high when the caloric value of the diet is markedly lowered. These special aspects of undernutrition are dealt with in other chapters. The general

effects of inanition are those of chronic partial starvation. Among the chief of these are,

(1) Reduction in body weight—emaciation. The body attempts to make up the caloric deficiency by burning its own tissues. The loss of weight is due chiefly to loss of fat, but also in severe instances to a loss of protein. The nitrogen balance is negative. In children growth is retarded. The positive nitrogen balance is smaller than normal, it may even be negative. In the less severe grades of undernutrition in children the growth impulse continues to cause an increase in height of the skeleton but the muscles and the breadth of the body are poorly developed.

(2) Reduced B.M.R. down to 70 per cent or less of the normal, subnormal body temperature and lowered blood pressure. The subject is abnormally sensitive to cold, due to the fact that the skin vessels are constricted in an attempt to reduce the dissipation of heat through radiation and convection (p. 624). The skin temperature upon which our thermal sensations depend is therefore lowered. The specific dynamic response to food is increased.

(3) The subject is readily fatigued, there are mental apathy and a lack of a zest for physical exertion. Work is performed with the same expenditure of energy as normally, so, though energy is economized in the carrying on of the vital processes as shown by the reduced B.M.R. and cold skin, no economy is effected in the execution of muscular work.

(4) The loss of internal fat which normally serves to support the organs—stomach, kidneys, uterus, etc.—against the effect of gravity, results in their displacement (visceroptosis). The lost body fat is partially replaced by water.

(5) Susceptibility to infections, "Fever and plague dog the footsteps of famine."

(6) Depletion of the plasma protein with resulting edema (war or hunger edema).

CHAPTER LIII

METABOLISM IN MUSCULAR ACTIVITY

THE CHEMICAL PHYSIOLOGY OF MUSCULAR CONTRACTION

The mechanical response of an isolated muscle to stimulation is not accompanied by an increased consumption of oxygen; extra oxygen is not consumed until after contraction and relaxation are over. So, there are two phases in the contraction cycle, an *anaerobic (anoxidative) phase* and an *aerobic (oxidative) or recovery phase*, during which the muscle is restored to its previous state. If the muscle be stimulated repeatedly in an atmosphere of nitrogen it contracts forcibly at first, but soon becomes fatigued, since it cannot obtain the oxygen necessary for its recuperation between the individual contractions. Lactic acid accumulates and the muscle enters into rigor. If at the onset of fatigue, oxygen is re-admitted the lactic acid disappears, and the muscle recovers its original power to contract. The lactic acid concentration at which complete fatigue of skeletal muscle ensues (lactic acid maximum) is from 0.3 to 0.6 per cent. The lactic acid is derived from the breakdown of glycogen (p. 614). As the lactic acid concentration rises the carbohydrate stores diminish. Yet, the onset of fatigue is not due to the exhaustion of the glycogen stores, for the muscle fails to contract before the latter have disappeared. It is more likely that the high acidity inhibits the enzymes through whose action glycogen breakdown is brought about. Phosphoric acid also accumulates in a muscle contracting in the absence of oxygen. The phosphoric acid production rises rapidly during the earlier contractions, soon reaches a maximum and then ceases.

That a muscle can contract anaerobically has been known for many years. It has also long been known that lactic acid and CO_2 are produced by a muscle contracting in nitrogen. Spallanzani 150 years ago observed that snails placed in nitrogen evolved CO_2 . In spite of these earlier observations it was thought, nevertheless, that a muscle derived its energy from oxidative processes—for how otherwise was the CO_2 produced? In order to explain the phenomenon it was supposed (Hermann, Pflüger) that an oxygen store was contained in some giant molecule (termed “inogen” by Hermann) within the muscle substance itself. So “intramolecular” oxygen was spoken of as the hidden

oxygen reserve from which the muscle drew for its anaerobic contraction. Lactic acid also, it was thought, was derived from the breakdown of this hypothetical molecule. This theory was disproved by the classic experiments of Fletcher and Hopkins in 1907. These observers showed that the CO_2 which appeared during the anaerobic contraction was not the result of oxidation but was *preëxisting* CO_2 —i.e., simply CO_2 which had been liberated by the action of lactic acid upon sodium bicarbonate in the muscle fluids. They showed that the oxidative processes occurred after the contraction was over, that lactic acid then disappeared and CO_2 was formed. It was erroneously supposed at this time that the lactic acid which disappeared had been *completely* oxidized to CO_2 and water. That glycogen was the lactic acid precursor was indicated by the fact that the appearance of lactic acid in muscle fatigued in nitrogen was proportional to the glycogen loss. Also an R.Q. of around unity, found later by Meyerhof for the recovery phase of isolated muscle, indicated that its fuel was carbohydrate.

Meyerhof also showed that when oxygen was admitted to a fatigued frog's muscle, the amount of gas consumed was only one-fifth of that expected if the disappearance of the lactic acid were due to its oxidation to CO_2 and water. The heat produced during the oxidative phase was also much less than it should be were all the lactic acid burned. It was found, further, that glycogen *increased* in the fatigued muscle recovering in oxygen.

Embden had previously shown the importance of phosphate in the activity of muscle. Increased excretion of phosphate in the urine occurs as a result of muscular exercise, and Embden found that when muscle juice was incubated with a solution of bicarbonate lactic acid and free phosphoric acid appeared in nearly equimolecular amounts. He suggested that the *immediate* precursor of lactic acid was a hexose-phosphate. This he termed *lactacidogen*. A hexose-phosphate had been shown by Harden and Young to be formed as an intermediary in the fermentation of sugar by yeast. When Embden added this ester to muscle juice an increased formation of lactic and phosphoric acids occurred. He also claimed to have demonstrated an increased production of phosphoric acid in a muscle during its contraction. The phosphoric acid as well as the lactic acid was believed to be derived from the breakdown of *lactacidogen* (i.e., hexose-phosphate). It will presently be pointed out, however, that the phosphoric acid of muscle is derived mainly from phosphocreatine.

THE CARBOHYDRATE CYCLE

Before describing the other changes which occur during contraction a summary of what may be termed the carbohydrate cycle will be given.

During the anaerobic phase of contraction, lactic acid is produced from glycogen through the intermediary of a phosphorus-sugar compound—hexose-phosphate.

In the recovery phase oxygen is consumed and about one-fifth of the lactic acid (or its equivalent) is oxidized, presumably to furnish energy for the resynthesis of the remaining four-fifths or so to glycogen.

The intermediary reactions involved in the breakdown of glycogen to lactic acid are not shown in the foregoing scheme. Evidence for the anaerobic chemical changes about to be outlined has been obtained very largely from studies of the enzyme systems in aqueous extracts of muscle and in yeast juice during alcoholic fermentation.

Through the action of the enzyme *phosphorylase* glycogen is broken down to glucose which undergoes esterification with inorganic phosphate to form glucose monophosphate—*glucose-1-phosphate*. *Adenosinetriphosphate* (ATP) acts as a co-enzyme (p. 615) in this reaction, giving up phosphate and being converted to *adenosinediphosphate* (ADP). Glucose-1-phosphate by intramolecular rearrangement is converted to *glucose-6-phosphate* through the action of *phosphoglucomutase*. Glucose-6-phosphate reacts with ADP, which gives up phosphate with the production of *adenylic acid* (adenosine monophosphate) and *fructose-1-6-diphosphate*.

Fructose diphosphate yields a molecule each of *dihydroxyacetone phosphate* and *3-phosphoglyceraldehyde*.

Dihydroxyacetone phosphoric acid

3-phosphoglyceraldehyde

Dihydroxyacetone phosphoric acid, through reduction, is converted to *glycerophosphate*; phosphoglyceraldehyde is oxidized to *phosphoglyceric acid*.

Glycerophosphoric acid

Phosphoglyceric acid

Phosphoglyceric acid is converted to *enol-phosphopyruvic acid*.

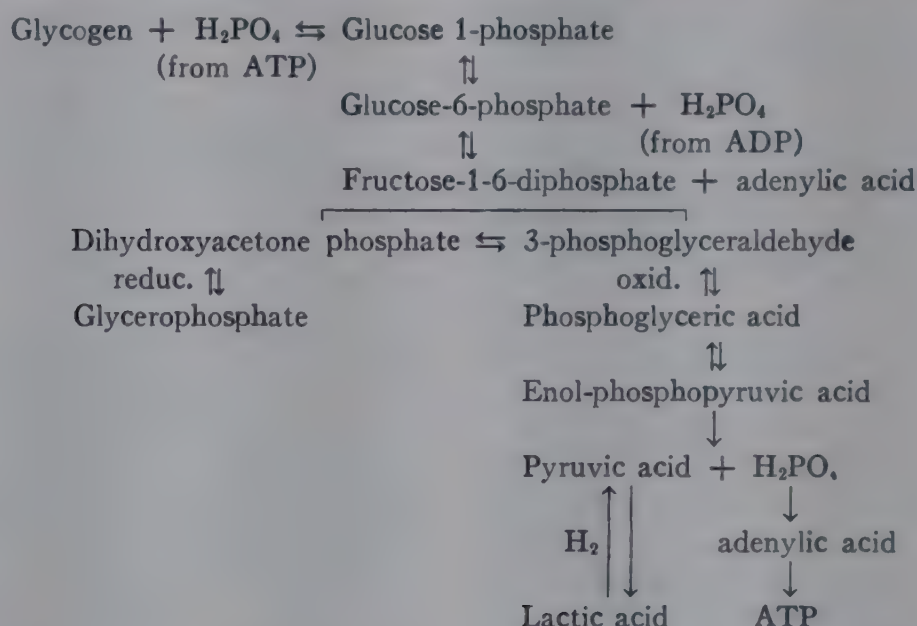

Enol-phosphopyruvic acid

Phosphopyruvic acid reacts with adenylic acid (formed, as mentioned above, in the phosphorylation of glycogen) with the production of pyruvic acid and ATP. The pyruvic acid reacts with phosphoglyceraldehyde through the action of *cozymase*, and is reduced to lactic acid; phosphoglyceraldehyde is oxidized to phosphoglyceric acid. As pyruvic acid is produced, it reacts with the phosphoglyceraldehyde which is furnished continuously during contraction by the breakdown of fructose diphosphate. The equilibrium dihydroxyacetone phosphate \rightleftharpoons phosphoglyceraldehyde,

shifts to the right when pyruvic acid first appears, there being little further production of dihydroxyacetone phosphoric acid.

The reactions just described are summarized in the following scheme modified from Meyerhoff.

All these reactions are reversible, with the possible exception of that between enol-phosphopyruvic acid and adenylic acid and the formation of ATP. Evidence derived from the use of isotopic phosphorus is against this reaction being reversible.

THE RÔLE PLAYED BY PHOSPHOCREATINE (PHOSPHAGEN)

Until the last few years no reactions of importance other than those just given (the carbohydrate cycle) were believed to be associated with the contractile mechanism. The glycogen \rightarrow lactic acid conversion was considered to be the *immediate* source of muscular energy. This view has been revised as a result of the following observations. In 1927 Eggleton and Eggleton obtained from muscle an organic compound of phosphoric acid. During contraction this compound breaks down liberating phosphoric acid which in the absence of oxygen accumulates in the muscle. The Eggletons therefore called it *phosphagen*. Fiske and Subbarow about the same time isolated a compound of phosphoric acid which they called *phosphocreatine*. This is also known as creatine phosphoric acid and is identical with the phosphagen of the Eggletons. It has the following formula:

In the presence of oxygen the phosphoric acid and creatine are resynthesized to phosphagen. In the muscle deprived of oxygen the resynthesis is incomplete.

Phosphoarginine is the corresponding phosphagen in invertebrate muscle.

In the muscles of some species both compounds are present.

Contraction without lactic acid production

An experiment of Lundsgaard (1929) has revealed the essential importance of phosphocreatine in the contractile process. He found that after the injection of sodium iodoacetate into the dorsal lymph sac of a frog, violent contractions of the muscles occurred followed by rigor. When a muscle of the poisoned animal was isolated and stimulated electrically in nitrogen it responded, but *no lactic acid was produced*. After about 10 contractions, it became fatigued. This is much sooner than the onset of fatigue in normal muscle and, unlike the latter, the poisoned muscle became slightly *alkaline* in reaction. About 0.5 mg. of lactic acid per gram of tissue is formed in a normal muscle after a similar number of contractions.

Upon analysis the poisoned muscle shows a loss of glycogen, and of phosphocreatine, and an increased content of hexose-phosphate. The lactic acid and phosphocreatine-phosphorus values of normal and poisoned muscles after 150 contractions each are shown in the following table (after Lundsgaard).

		Lactic acid mg. per cent	Phosphagen phosphorus mg. per cent
Normal	Resting.....	25	61
	Working.....	84	40
Poisoned	Resting.....	16	57
	Working.....	15	0

It was concluded that the greater quantity of phosphocreatine in the working normal as compared with the poisoned muscle was not the result of a reduced breakdown of this substance but rather of its resynthesis. The energy for resynthesis, it was suggested, was derived from the glycogen \rightarrow lactic breakdown. The energy which could be derived from the production of one gram of lactic acid, and its neutralization by the muscle proteins is 280 calories. In the foregoing experiment about 0.06 gram (61 mg.) of lactic acid was formed by the normal muscle. This exothermic reaction would therefore furnish $0.06 \times 280 = 16.8$ calories. In the resynthesis of phosphocreatine from phosphoric acid and creatine heat is absorbed (endothermic reaction). The resynthesis of 40 mg. as in the above experiment would require 16.5 calories, i.e., about the same quantity of heat as was given out in the production of 0.06 gram of lactic acid. Evidently, the reason for the complete disappearance of the phosphocreatine from the poisoned muscle is the failure of its resynthesis, and this in turn is due to the failure in lactic acid production. The breakdown of glycogen to hexosephosphate is not prevented by iodoacetic acid; the drug inhibits oxidation and reduction, hence dihydroxyacetone phosphoric acid breakdown is halted. Thus the poison destroys the carbohydrate mechanism which is essential for driving the phosphocreatine cycle. The poisoned muscle when stimulated in oxygen loses its phosphagen more slowly, and so fatigues less readily.

THE RÔLE PLAYED BY ADENOSINETRIPHOSPHATE ACID IN MUSCULAR CONTRACTION

Muscle contains the nucleotide (p. 565) adenosinetriphosphate (also called adenylyl pyrophosphate). This is a compound of adenine, d-ribose and three molecules of orthophosphoric acid. The following formula has been proposed for it by Lohmann.

Adenosinetriphosphate [Adenyl-pyrophosphoric acid]

It breaks down into one molecule of phosphoric acid and adenosinediphosphate. By the removal of a second molecule of phosphoric acid the latter is converted to adenylic acid (adenosinemonophosphate). A part of the latter undergoes deamination with the production of small amounts of ammonia and possibly of inosinic acid (hypoxanthine nucleotide). The decomposition of adenosinetriphosphate occurs at the very commencement of the contraction, i.e., preceding

the breakdown of glycogen. Though ammonia is liberated only in very small amounts, during moderate muscular activity, in fatigued or injured muscle as much as 3 mg. per gram of muscle may be produced.

The ammonia production and the breakdown of phosphocreatine into its components, which act as buffers (creatine and sodium phosphate being more alkaline than phosphocreatine) prevent the rise in acidity in the muscle fiber which otherwise might be expected to result during contraction. Actually, little change in reaction occurs. The slight but definite alkalinity noticeable in muscle poisoned with iodoacetate is due to the breakdown of phosphocreatine unaccompanied by lactic acid production.

Adenosinetriphosphate in the presence of Mg ions acts as a coenzyme serving as a donator and an acceptor of phosphate; in its absence phosphorylase is completely inactive. Adenosinetriphosphate when it breaks down yields adenosinediphosphate and phosphate for the esterification of glucose molecules derived from the breakdown of glycogen. Dephosphorylation of adenosinediphosphate, with the production of adenylic acid, is brought about by a separate reaction. Energy for the resynthesis of adenosinetriphosphate is derived from the breakdown of phosphocreatine which also furnishes the necessary phosphate. Energy and phosphate for the resynthesis of the latter are derived, it is believed, from the degradation of phosphopyruvate, ADP and ATP acting as intermediaries in the transference of phosphorus.

The muscle protein *myosin*, or some substance indistinguishable from it, was shown by Engelhardt and Ljubimowa in 1939 to act enzymatically, catalyzing the dephosphorylation of adenosinetriphosphate with the production of adenosinediphosphate. The degradation of the latter to adenylic acid and phosphate is caused by a different enzyme associated, apparently, with the soluble muscle proteins. Needham and his associates

have advanced a tentative theory based upon the surprising discovery that myosin, which it will be recalled composes the contractile fibrils of muscle, is an enzyme. They suggest that in the resting muscle adenosinediphosphate accepts phosphate from phosphocreatine to form adenosinetriphosphate; the latter then donates phosphate to myosin, the phosphorylated protein molecule then assuming the elongated or extended form. Upon excitation of the muscle myosin liberates

phosphate, the shortened or contracted form of the molecule then resulting. Myosin or *adenosinetriphosphatase*, as it may appropriately be called, is activated by Ca ions and to a less degree by manganese ions. Bailey suggests the possibility that the first effect of stimulation of muscle is to make activating Ca ions available for the myosin composing the contractile fibrils. This theory, though admittedly lacking in detail, arouses unusual interest since it attempts to link the chemical processes in muscle with the mechanical changes.

It is now widely believed that adenosinetriphosphate itself is the immediate source of the energy for contraction, and that it is resynthesized by the energy liberated in the subsequent breakdown of phosphocreatine.

SUMMARY OF THE CHEMICAL CHANGES ASSOCIATED WITH MUSCULAR CONTRACTION

The series of chemical changes which probably occurs may now be given in natural sequence. The first reactions are the breakdown of adenosinetriphosphate to *adenylic acid* and *phosphoric acid* which becomes engaged simultaneously in the phosphorylation of glycogen; fructose *diphosphate* is formed. *Phosphocreatine* next breaks down, yielding *creatine* and *phosphoric acid* which immediately joins with the adenylic acid formed in the previous reaction, adenosinetriphosphate being resynthesized. The fructose diphosphate gives rise to *dihydroxyacetone phosphoric acid* and phosphoglyceraldehyde, and the series of reactions of the carbohydrate cycle indicated on pp. 613 and 614 follows. The total energy derived from

oxidation of the remainder of the lactic acid. In fatigue, the accumulation of lactic acid slows and then arrests the glycogen \rightarrow lactic acid breakdown and, as a consequence, phosphocreatine resynthesis is prevented. Lactic acid production, therefore, though not directly furnishing the energy for contraction, serves to "wind up" the contractile mechanism or, if one may compare it to a storage battery, to recharge it. Adenosinetriphosphate is the immediate source of the energy for the contraction. The reversible reactions are dependent upon an enzyme system in the muscle; adenosinetriphosphate, in the presence of magnesium ions, acts as a co-enzyme serving as an intermediary in the transference of phosphate.

That the production of lactic acid is not the immediate source of the energy for contraction is proved by the following facts:

(a) Contraction of the muscle occurs before lactic acid is produced.

(b) A muscle, poisoned with iodoacetate, continues to contract for a time though no lactic acid is formed. Also, an unpoisoned muscle will contract after the glycogen stores have been exhausted.

(c) The greater part of the lactic acid is produced after the contraction is over, i.e., in the recovery phase, and it is probable that none is produced during the first one or two of a series of rapid twitches.

The energy exchanges are summarized in the following scheme:

(a) Adenosine triphosphate \rightarrow	phosphoric acid + adenylic acid	energy for contraction
(b) Phosphocreatine \rightarrow	creatine + phosphoric acid	energy for resynthesis of adenosine-triphosphate
(c) Glycogen to lactic acid		energy for resynthesis of phosphocreatine
(d) Oxidation of part of lactic acid (about $\frac{1}{2}$)		energy for resynthesis of the remainder of the lactic acid to glycogen

the conversion of glycogen to lactic acid is utilized for *phosphocreatine resynthesis* which takes place partly (about $\frac{1}{2}$) in the anaerobic phase and partly (about $\frac{1}{2}$) in the aerobic phase. The phosphoric acid for the resynthesized phosphocreatine is obtained from the breakdown of phosphopyruvic acid by way of adenosinetriphosphate. Thus phosphate borrowed from adenosinetriphosphate for the phosphorylation of glycogen is given up for the resynthesis of phosphocreatine. Of the lactic acid formed, a part is resynthesized to glycogen, the energy for the resynthesis being derived from the

Before concluding this account of the chemical changes underlying muscular contraction, the views of Sacks and his associates which are opposed to those of the Embden-Meyerhof-Lundsgaard school should be briefly mentioned.

Sacks denies that the anaerobic processes as revealed by analyses of cell-free extracts of isolated muscle, and upon which the Embden-Meyerhof-Lundsgaard scheme is largely based, give a true picture of what occurs in muscle with its circulation intact. He contends that the primary source of the energy for contraction is the oxidation of glycogen to lactic acid

without phosphorylation. That is to say, hexose-phosphate is not an intermediary in the formation of lactic acid except when the oxygen supply is inadequate. In the intact muscle the anaerobic mechanism is resorted to at the commencement of the contraction or at any other time that the circulation fails to supply the required amount of oxygen. During the steady state (p. 619) energy is furnished by direct oxidative reactions; anaerobic processes are then dispensed with. Sacks found that adenosinetriphosphate and phosphocreatine are resynthesised slowly, too slowly he believes to furnish energy for continued muscular activity. It is also claimed that the chief role of phosphocreatine is the neutralization of lactic acid. Furthermore, Sacks, using the radioactive isotope of phosphorus as a "label", could obtain no evidence of exchanges of phosphate between adenosinetriphosphate and phosphocreatine during the contraction of the cat's gastrocnemius under anaerobic conditions. He concludes that these substances do not act as intermediaries in the production of lactic acid within the muscle cell.

Some support for these views has been furnished by the experiments of Flock, Ingle and Bollman. They stimulated the weighted gastrocnemii of rats, circulation to the muscles remaining intact. The rate of stimulation was 3 per second. At the end of periods of stimulation, varying progressively in length, the muscles were rapidly frozen with carbon dioxide ice, fragmented and analyzed. During the first minute of work compounds associated with anaerobic activity, such as lactic acid, inorganic phosphate and hexose monophosphate accumulated rapidly; glycogen, phosphocreatine and adenosinetriphosphate decreased. The concentration of the last mentioned declined more slowly than the concentrations of the other two, a fact which the authors take as an indication that, contrary to the general belief, the hydrolysis of adenosinetriphosphate does not precede the breakdown of glycogen. As the work continued and a steady state was reached, the concentrations of adenosinetriphosphate and phosphocreatine remained unchanged; the concentrations of hexosemonophosphate and lactic acid returned to their resting levels. Flock and his associates conclude that the absence of any significant change in concentrations of the labile substances, once a steady state has been reached, gives evidence against their serving as a source of energy in continued muscular work. The removal of lactic acid they attribute to diffusion into the blood stream rather than to oxidation or resynthesis locally.

HEAT PRODUCTION IN MUSCLE

In the case of a muscle contracting isometrically, i.e., without shortening, all the energy which it expends appears as heat. If, on the other hand, the muscle is allowed to shorten and lift a weight, from 20 to 25 per cent of the total energy expenditure on the average, and under optimal conditions

30 per cent, appears as mechanical work. The efficiency of the muscular machine,

$$\frac{\text{mechanical work performed}}{\text{energy expenditure over the basal level (resting state)}}$$

is therefore much higher than that of the steam engine (7 to 20 per cent) and is comparable to that of the best types of gas engine (25 to 30 per cent).

The heat production of a muscle contracting isometrically in *nitrogen* shows four phases.

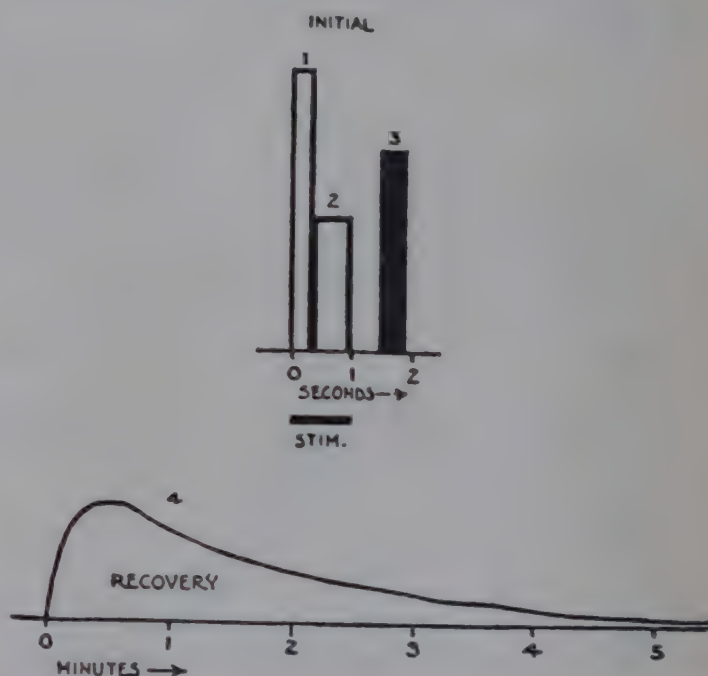

FIG. 239. Showing the stage of heat production of muscle during and following a short tetanic contraction. The first three stages represent the initial heat. 1, the contraction heat; 2, the heat produced during the maintenance of contraction; 3, the relaxation heat. The fourth stage (4) is the recovery heat. (From Evans, *Recent Advances in Physiology*.)

- (1) A large outburst of heat at the commencement of the contraction
- (2) A *sustained* heat production during contraction (tetanus)
- (3) A small outburst during relaxation—*relaxation heat*
- (4) A small amount of heat produced after contraction and relaxation are over. This so-called *delayed anaerobic* heat may continue to be produced for some considerable time.

The first three of these together are called the *initial heat* (figs. 239 and 240). In a single twitch (2) is not evident. The first outburst of heat and, in the case of a tetanus, the intermediary or sustained heat constitute the waste heat of chemical

reactions. The outburst during the relaxation or third phase is caused by the degradation to heat of the energy exhibited as tension during contraction; it amounts to about 35 per cent of the entire initial heat. This initial heat is also produced when a muscle contracts in oxygen but it is evolved in the anaerobic phase, i.e., it is independent of oxidative processes.

FIG. 240. Curve of initial heat developed in a single twitch at 0°C. The dotted line starting at 0.25 second, when the tension begins to fall, suggests the correct start for the heat due to mechanical relaxation.) After Hartree.)

The total heat production of a muscle contracting in oxygen is over 2.2 times greater than that of one contracting in nitrogen, for there is the added heat of oxidative processes—the *oxidative heat*. The delayed anaerobic heat plus the oxidative heat is referred to as the *recovery heat*. Thus the total heat evolved during normal contraction is made up as follows:

Initial heat:

- (1) Contraction heat
- (2) Relaxation heat

Recovery heat:

- (1) Delayed anaerobic heat i.e., heat of lactic acid production over that of phosphagen synthesis
- (2) Oxidative heat, i.e., heat of oxidative processes over that absorbed in resynthesis of glycogen

In a muscle poisoned with iodoacetic acid and contracting in nitrogen, the different phases of the initial heat and its total amount do not differ from those occurring in a normal muscle. Yet lactic acid production has been abolished. In such a case the initial heat production is apparently due mainly to the breakdown of phosphocreatine and adenylypyrophosphate—an explosive liberation of heat. In the normal muscle, on the other hand, lactic acid production and its neutralization by the muscle proteins causes a pronounced evolution of heat (exothermic reaction). Why then are the initial heats the same in both instances? Presumably, in the case of the normal muscle, the heat of lactic acid production and neutralization are masked being absorbed in the synthesis of phosphocreatine and adenylypyrophosphate (endothermic reaction). In either case it is believed that the initial heat represents the balance of heat production over heat absorption.

The recovery heat is also the resultant of exothermic and endothermic reactions—lactic acid oxidation and glycogen resynthesis. There is also the delayed anaerobic heat. It has been mentioned that a proportion of the lactic acid production occurs after the contraction is over, and that a proportion of the phosphocreatine resynthesis also occurs at this time. For a long time no explanation for the anaerobic delayed heat was forthcoming. It now appears that it, like the initial heat, represents a balance between the heat evolved during delayed lactic acid production and that absorbed by phosphagen resynthesis. The heat of recovery therefore is made up of this delayed anaerobic heat plus the balance between lactic acid oxidation and glycogen resynthesis.

MUSCULAR CONTRACTION IN THE INTACT ANIMAL

Oxygen debt

We have seen that an isolated muscle is able to contract when stimulated in an atmosphere of nitrogen but its recovery phase is postponed until oxygen is re-admitted. During strenuous exercise the muscles of the intact animal behave similarly. While contracting actively they are unable to obtain sufficient oxygen for the removal (by oxidation and resynthesis to glycogen,

arbitrary units	
(1) Contraction heat	0.65
(2) Relaxation heat	0.35
Total initial heat	1.0
(1) Delayed anaerobic heat i.e., heat of lactic acid production over that of phosphagen synthesis	0.08
(2) Oxidative heat, i.e., heat of oxidative processes over that absorbed in resynthesis of glycogen	1.16
Total recovery heat	1.24
Total heat	2.24

of the large quantities of lactic acid produced. Complete recovery must be postponed until the exercise is over, when the accumulated lactic acid is gradually removed. The muscles of the intact animal during strenuous exertion are therefore comparable to the isolated muscle contracting anaerobically. It was shown by A. V. Hill and his associates that an athlete during great muscular effort such as sprinting cannot possibly inhale more than a fraction of the oxygen required. That is, the body works its muscles but does not furnish them with the total oxygen required for the work until some time after this has been completed—it “goes into debt for oxygen” paying up during the recovery period (see fig. 241). In a hundred yard sprint, for example, the oxygen requirement may be over 6 liters. It is obviously impossible to deliver this amount to the muscle

FIG. 241. Illustrating the increase in O_2 consumption above the resting level following exercise—“oxygen debt.” (From Hill, *Muscular Movement in Man*.)

in the few seconds in which the race is run. The maximum consumption possible is not more than 4 liters of oxygen per minute. Furthermore, a sprinter can dash 100 yards with the breath held. The great value of the anaerobic phase of muscular contraction is thus revealed. Through the ability of the muscles to contract when deprived of oxygen and to replenish their stores of energy during the phase of oxidative recovery, they are enabled to perform for short periods an amount of work which otherwise would be impossible, that is, were they as in the case of a motor engine dependent entirely upon a contemporaneous oxygen supply.

The oxygen debt is determined by measuring the oxygen used during the period of recovery, i.e., from the termination of the exercise to the time when the oxygen consumption has returned to normal, and subtracting from it the quantity of oxygen used during a corresponding resting period. The length of the recovery period may be 80 minutes or more. In very severe exertion the oxygen debt amounts to over 10 liters (or about 0.3 cc. per gram of muscle tissue). The maximum

recorded in man is over 18 liters. During less strenuous exercise the discrepancy between lactic acid production and lactic acid removal is less pronounced, and the oxygen debt is correspondingly smaller. In light exercise the lactic acid is removed during the work—the body “pays as it goes,” and no oxygen debt is incurred. This is called the *steady state*. In other words, anaerobic and aerobic processes are balanced. The average man cannot maintain the steady state unless the oxygen requirement of the work does not exceed about 2 liters per minute. After severe exercise the normal level of lactic acid in the blood may not be reached until an hour or more after the exercise has ceased.

Lactic acid production during exercise

The lactic acid produced in a short bout of strenuous exercise may amount to as much as 3 grams per second, and its concentration in the blood rise as high as 0.2 per cent. The lactic acid, though buffered by the muscle protein thus

and to a less extent by phosphates and bicarbonates, causes a sufficient change in blood reaction to stimulate powerfully the respiratory center. Large amounts of carbon dioxide are “blown off” from the lungs.

Hill and Lupton have taken the excess oxygen consumed during recovery as a basis for calculating the quantity of lactic acid present in the body at the end of exercise. They assumed that the recovery oxygen was used entirely in the oxidative removal of lactic acid, and that the quantity of lactic acid removed by oxidation was, as in the case of isolated muscle, only about one-fifth of the total quantity which disappeared. Thus;

That is, for every 3 molecules of oxygen consumed during recovery 1 molecule of lactic acid has been oxidized, and for every molecule of lactic acid oxidized 4 have disappeared through synthesis to glycogen. Three gram molecules of oxygen consumed therefore represent the disappearance of 5 gram molecules ($90 \times 5 =$) 450 grams of lactic acid. Or, 1 gram molecule (22.4 liters) of oxygen represents the disappearance of $\frac{5}{3}$ gram molecules (150 grams) of lactic acid. Each liter of oxygen consumed during recovery would therefore indicate the disappearance of $\left(\frac{150}{22.4} = \right)$ 7 grams, approximately, of lactic acid.

The process of removal of the lactic acid is not confined to the muscles in which it arises. The liver, heart, brain and muscles not actually engaged in the exercise, share in the process the lactic acid being carried to them in the blood. Barr and Himwich showed this in animal experiments. From the results of their experiments upon rabbit muscle with intact nerve and blood supply, Sacks and Sacks conclude that, contrary to what is believed to occur in isolated frog muscle, lactic acid is not resynthesized to glycogen in the mammalian muscle during recovery, but diffuses into the circulation to be mainly converted in the liver to glycogen. A smaller part is oxidized by brain,

to the Ringer's something like 10,000 twitches can be evoked and a total tension of 6 tons per square centimeter of cross section of the muscle developed. It cannot, however, be concluded from experiments upon the isolated frog muscle, which for one thing is poorly supplied with oxygen, that the muscle of the intact mammal can use only carbohydrate fuel. Himwich and Rose, for example, by determinations of CO_2 and of O_2 of venous and arterial bloods of intact muscles obtained an average R.Q. of only 0.80. Attempts to decide the question for the intact body have been made by determinations of the respiratory quotient of the *excess metabolism of exercise* in man. The results are

FIG. 242. Curve of the R.Q. of the excess metabolism caused by muscular exercise. (From Hill, *Muscular Movement in Man*.)

heart and probably by other tissues as well. If produced in large amounts, as in strenuous exercise, an appreciable amount finds its way into the urine.

The fuel of exercise

We have seen that in the case of isolated frog muscle the respiratory quotient is around unity, which indicates that the ultimate source of the energy for the contractile process is mainly if not entirely carbohydrate. That is, the energy required to restore the muscle to its pre-contraction state is derived from the oxidation of this food material. Though the glycogen of the isolated muscle is reduced by activity no diminution of its fat content has been demonstrated. It has also been shown that if an isolated muscle be stimulated while suspended in Ringer's solution so that the lactic acid as it forms may diffuse away, fatigue sets in only when the glycogen stores have been exhausted (see p. 612). If glucose be added

however, difficult to interpret and no definite conclusion can be drawn from them.

The excess metabolism of exercise is determined from the oxygen consumed (or of the CO_2 eliminated) during the work and recovery periods less the amount of oxygen used (or CO_2 eliminated) during a corresponding period preceding the exercise. The ratio between the excess quantities of the two respiratory gases will, of course, be the respiratory quotient of the excess gaseous exchange. But certain precautions must be taken in order to obtain the true respiratory quotient, i.e., the respiratory quotient of the oxidative processes, for as already mentioned a large proportion of the CO_2 which is eliminated following exercise is not oxidative in origin but is simply gas which has been liberated from chemical combination (p. 612). The period of increased CO_2 elimination and high R.Q. immediately following the exercise is followed by one in which the output of the gas is reduced and the R.Q. is well below the normal level of 0.85— CO_2 is being retained to replenish the bicarbonate stores (fig. 242). During a period of sufficient length, therefore, one effect (retention) will

st balance the other (blowing off) and the quantity of O_2 eliminated during this time in excess of the output during a pre-exercise period will be the extra quantity actually produced by oxidative processes. This value is used in calculating the R.Q. of the excess metabolism resulting from the exercise.

In experiments on man involving short periods of strenuous exercise, the R.Q. of the excess metabolism has been found by several observers to rise above that of the resting period and to reach or exceed unity. For example, Rest, Furusawa and Ridout obtained a respiratory quotient of between 1.18 and 1.68 for very arduous exercise. For less strenuous work the R.Q. was around unity and for mild exercise it was considerably lower—little above that for the rest period. The degree of exercise required to raise the quotient to unity varied in different subjects. The very high quotients (above unity) which these observers obtained have since been observed by others, but Gemmill in more rigidly controlled experiments in which the subject was kept under basal conditions for a period of several hours preceding the exercise, obtained an average respiratory quotient for the excess metabolism of a little less than unity. Determinations of the oxygen consumption and carbon dioxide elimination were made over a recovery (post-exercise) period of 3 hours.

The R.Q. of the excess metabolism has also been determined by several workers upon diets high, respectively, in fat or carbohydrate. Benedict and Cathcart, for example, found an R.Q. of 0.90 on a carbohydrate-rich diet and one of 0.82 (indicating the utilization of fat) on the fat-rich diet. They concluded that the fuel of exercise was not exclusively carbohydrate but depended largely upon the previous diet. Krogh and Lindhard decided that the food material oxidized during work was the same as that during rest and that in either case the relative quantities of fat and carbohydrate oxidized varied with their proportions in the diet. Work, however, was performed less economically (by 10 per cent) upon fat than upon carbohydrate.

Carpenter and Fox carried out two comparable groups of experiments. In one group 50 grams of glucose were given just prior to the commencement of the exercise. In the other group the subjects were fasting. The R.Q. of the excess metabolism of those which had received the glucose was considerably higher than those of the other group.

Anderson and Lusk obtained in a starving dog working a treadmill respiratory quotients suggestive of the combustion of fat, namely, from 0.71 to 0.73. Also in prolonged severe exercise in man Talbot and associates observed a fall in the R.Q. following an earlier rise.

Other lines of approach have yielded more important evidence for carbohydrate being the main fuel, though not necessarily the only one, used in muscular work. Other food-stuffs, especially fat can serve under certain circumstances, the propor-

tion of each which undergoes oxidation varying with the amount available and the severity of the exercise. In *short periods of light exercise* it is probable that the energy is derived from the oxidation of materials of the same nature as those which furnish energy during rest. These are small molecules of carbohydrate, fat and protein material already present in the circulation (Carpenter). Such materials are soon exhausted, however, by heavier work when the glycogen reserves are drawn upon. In *short and strenuous* bouts of exercise there is general agreement that the main fuel burned is carbohydrate. In a marathon race, for example, the call made upon the available sugar may result in hypoglycemia, and in endurance tests with animals it has been found that those given sugar can perform about three times as much work as they are capable of when on an ordinary diet. The administration of glucose at the commencement of the race prevents the fall in blood sugar and exerts a definitely beneficial effect upon the athlete's performance. The production of large quantities of lactic acid in strenuous muscular exercise also points to carbohydrate material as the source of energy. In *prolonged exhausting exercise* the carbohydrate stores become depleted; fat is then used largely to drive the muscular machine; the R.Q. falls. It is likely that the fat is oxidized directly and need not be converted first to carbohydrate. It is still uncertain whether such a conversion occurs.

The use of protein as fuel has been a subject of controversy for a number of years. It has been common teaching that this food material, except in minimal quantities when fat and carbohydrate are unavailable is not a source of energy for muscular work, but served merely to repair tissue "wear and tear." This conclusion was arrived at chiefly from studies of the nitrogen excretion. Ordinary exercise, for example, does not increase appreciably the output of nitrogen in the urine nor does it increase the non-protein nitrogen of the blood. More strenuous work causes a slight rise in the blood non-protein nitrogen and a moderate increase in the urinary nitrogen in man and in animals. In work experiments upon fasting dogs it has been calculated that at the most not more than 7 per cent of the energy required for the exercise could have been derived from protein; the great part of the energy had apparently been obtained from the combustion of fat. In prolonged starvation after exhaustion of the stores of carbohydrate and fat, protein (carbon part of the amino acids) must then, of course, serve as the sole source of energy.

It has been pointed out by Cathcart, however, that the nitrogen excretion during short periods of exercise

may not be a true criterion of protein metabolism since the nitrogen released in the breakdown of protein may be utilized in synthetic processes and consequently not appear in the urine. Or, muscle protein may be catabolized and its nitrogen excreted, yet if, as is quite possible, an equivalent amount of nitrogen derived from the food were diverted to the muscles to replace that which had been lost, the total nitrogen excretion would remain unchanged. This observer also considers that, in the long run, muscular work exerts a very definite influence upon protein metabolism and cites the familiar observation that persons engaged in heavy muscular work demand a diet rich in protein, particularly meat. It has also been shown by several investigators that a retention of nitrogen occurs during a period of training—apparently for the manufacture of muscular tissue.

Such views are in harmony with modern conceptions of protein metabolism (p. 545). Since catabolism and synthesis may go hand in hand the total quantity of nitrogen excreted gives no indication of the interchanges which are taking place between food and tissue nitrogen. It is scarcely reasonable to assume that after deamination the non-protein portions of the amino acids can not serve as a source of oxidative energy.

A carnivorous animal, for example, can subsist upon diet composed almost exclusively of protein. Canzulli and Rapport also draw attention to the irrelevance of the nitrogen excretion and insist that it can give no information respecting the non-nitrogenous part of the catabolized protein. From a study of the respiratory quotient of the excess metabolism of exercise performed by a dog on a high protein diet, they conclude that the oxidative energy for muscular exercise can be supplied quite as readily by protein as by carbohydrate or fat.

The question whether or not *alcohol* can furnish energy for muscular work has been investigated by a number of workers. The evidence has been conflicting. Some have reported that muscular exercise hastened the disappearance of alcohol from the blood, presumably by increasing combustion (see Mellanby). On the other hand, Carpenter and his associates in a recent careful study did not find that work exerted such an effect. They conclude that alcohol disappears from the human body at a uniform rate whether the subject is at rest or performing muscular exercise. Nor did muscular work alter the concentration of alcohol in the expired air (i.e. the amount eliminated per liter of CO_2 remained unchanged), in the urine or in the blood.

CHAPTER LIV

THE BODY TEMPERATURE. HEAT BALANCE

The temperature of the body in health as determined from a thermometer placed in the mouth is around 98.6°F. (37.0°C.). The rectal temperature is about a degree higher and the axillary about a degree lower than the mouth temperature. Some persons habitually have a body temperature a few tenths of a degree higher or lower than these figures. Variations in the body temperature also occur in the same individual throughout the day—a difference of 0.5° or even 1.0°F. occurring between the maximum in the late afternoon or early evening, and the minimum at about 4 or 5 o'clock in the morning. In night workers the times of the maximum and minimum temperatures may be reversed. The temperature of the internal organs is higher by 2° or 3°F. than the temperature of the skin. The temperature of the liver, for example, is about 100°F. whereas that of the skin covered with clothes is from 75° to 93°F. The temperature of the bare skin varies widely, of course, with the environmental temperature. The influence of the latter upon the temperature of the covered skin will depend upon the heat-insulating properties of the clothing, air movement (breeze, wind), atmospheric moisture, etc. Strenuous muscular exercise causes a temporary rise in body temperature of from 1.0° to 4.0°F. or more; a temperature of over 104°F. during exercise has been reported (L. Hill).

The heat regulating mechanisms are not fully developed at birth. The body temperature of the newborn child, though in general the same as that of the adult tends to be irregular and unstable. Spontaneous variations of from 1 to 2 degrees are common during the first year.

THE REGULATION OF BODY TEMPERATURE

Mammals and birds possess efficient mechanisms for maintaining a constant body temperature against extreme changes in environmental temperature. It is a remarkable fact that the temperature of a warm-blooded (homoiothermic) animal remains practically unchanged though the surrounding temperature may vary between 0°F. or less and 100°F. or upwards. On the contrary, the body temperature of a cold-blooded (poikilothermic) animal such as the frog, turtle, etc. is practically that of its environment (fig. 243).

The body temperature of the homoiothermic animal represents the balance struck by the heat

produced in the tissues (and heat acquired in warmed food) and the heat lost to the environment. Heat production is the result of chemical reactions and is therefore spoken of as the *chemical regulation* of body temperature. Heat loss is dependent upon physical (and physiological) factors—*physical regulation*.

PHYSICAL REGULATION—HEAT LOSS

Heat is lost from the body through

- (a) *Radiation, convection and conduction.*
- (b) *Evaporation of water from the lungs and skin.*
- (c) *Raising the inspired air to body temperature.*
- (d) *Urine and feces.*

Under the ordinary conditions of every day life over 95 per cent of the total heat loss occurs through (a) and (b). The heat lost in raising the temperature of the inspired air to body temperature (c) will, of course, vary with the air temperature, but at ordinary room temperatures it does not amount to more than 2 or 3 per cent of the total. The air is a very poor conductor, so in terrestrial animals conduction plays a very minor rôle except under special circumstances, as when the body is in contact with a cool object. Radiation is responsible for about 55 per cent of the total heat loss and convection for 15 per cent (see Table below). The heat lost in the urine and feces accounts for only 1 per cent or less of the total heat loss.

The total quantity of heat lost in twenty-four hours must, of course, just equal the amount produced; otherwise the body temperature would rise or fall. The heat production of an average man doing light work is about 3,000 Calories. The proportions of this which are dissipated through the various channels at ordinary room temperature are given in the following table, in approximate figures.

	Calories	Per cent
(a) Radiation, convection and conduction.....	2100	70
(b) Evaporation from skin and lungs.....	810	27
(c) Warming inspired air	60	2
(d) Urine and feces (i.e., heat of these excreta over that of the food).	30	1
Total daily heat loss..	3000	100

Radiation, convection and conduction

The loss of heat by these means varies with (a) the air temperature and other environmental conditions, e.g., humidity and air movement, (b) the nature and amount of clothing, and (c) the quantity of heat produced within the body, i.e., with the metabolism.

The rate of cooling of any warm object varies with the temperature of the air and of colder objects in contact with or near it. When a large temperature difference exists between the two, the warm object loses heat rapidly through radiation, conduction and convection, the rate of heat loss, however, becoming gradually less as the temperature of the object approaches that of the environ-

FIG. 243. Variation of body temperature of different types of animals by sojourn for two hours in an environment of 5° to 35°C. (After Martin.)

ment. The dead body behaves in a manner similar to that of any inanimate object, taking from ten to twenty hours on an average to reach the temperature of its surroundings. In the living body, on the other hand, factors operate to encourage or minimize heat loss, respectively, when the environmental temperature is high or low, or corresponding changes in the body's heat production occur. The factors involved in heat conservation or heat loss are dependent essentially upon reactions of the autonomic nervous system. The following are the principle adjustments which take place in the blood-vascular system. (a) *Redistribution of blood.* The cutaneous vessels dilate or constrict and through the diversion of blood from internal regions of the body to the surface, or from the surface to the internal organs, heat loss is increased or diminished, respectively.

At a temperature of 34°C. the quantity of blood circulating through the skin may, according to DuBois, amount to 12 per cent of the cardiac output. These changes may be initiated in one or a number of four ways, a change in temperature of the blood supplying the nervous centers; reflexly through centers in the brain and cord in response to change in skin temperature (stimulation of hot or cold spots, p. 798); through axon reflexes, and finally through responses of the vessels to direct stimulation by changes in external temperature. (b) *Variations in blood volume* (see p. 20). A rise in temperature causes an increase in blood volume; the blood is diluted by fluid drawn into the circulation from the tissues, chiefly the skin, muscle and liver. Blood is expelled from the spleen (p. 53). At low temperatures the blood volume is reduced, the blood becoming more concentrated, as shown by an increase in the percentage of blood solids. These changes in blood volume are of paramount importance in the regulation of body temperature. Barbour has shown that when a dog whose spinal cord has been sectioned in the lower cervical region, is immersed in a cold bath, concentration of its blood does not occur and its temperature falls. When a normal animal is exposed to cold in a similar manner, concentration of the blood occurs and the body temperature remains practically unchanged (fig. 244). (c) *Increased circulation rate* (p. 225).

The epidermis and the subcutaneous tissue when the vessels are constricted are a little more efficient as insulating material than a layer of cork of the same thickness (DuBois). The subcutaneous layer varies considerably in thickness in different persons and is thicker in women than in men. This accounts largely, no doubt, for the greater resistance of the former to low temperatures. For the same reason persons who are overweight, owing to the better insulation provided by the excess subcutaneous fat, are better able to withstand the cold than lean persons, but they also become more easily overheated when, as in muscular exercise, heat production is increased.

Convection, i.e., the rate of movement of warm air from the neighborhood of a heated object varies, of course, with the temperature of the atmosphere. The clothed body has a layer of warm moist air in contact with the skin which tends to become trapped in this situation and in the spaces of the clothing. In the absence of a temperature difference between it and the external air or of some movement to cause mixing, this air will remain practically stagnant. However, when the

atmosphere is cooler, convection currents are set up which mix the air lying against the skin with fresh air. Convection is essentially dependent upon the relative densities of airs at different temperatures, the warmer and lighter air rising, the cooler air falling. Dry air is denser than air possessing a high content of water vapor. One would expect therefore that changes in the humidity of the atmosphere should alter the heat lost by convection but, as a matter of fact, the relative hu-

nearly all infra-red¹ rays (up to 1 or 2 per cent) or absorbs to the same extent all rays which fall upon it (Hardy and Muschenheim). The radiating surface of the human body is only about 85 per cent of the total surface area, since skin surfaces such as in the axillae and between the legs which face one another or are actually in contact do not radiate heat to the environment. The main factor influencing heat loss through radiation is the temperature of surrounding objects relative to that of the skin. The body, for example, radiates heat to a block of ice but absorbs heat from a hot stove or radiator. It should be remembered that the air intervening between the body and the source of heat is not heated by radiant energy, but only by convection. Another factor, though a very minor one, is the humidity of the atmosphere. Air with a high water vapor content is more opaque to radiant heat than dry air. Heat lost through radiation is therefore slightly reduced when the relative humidity is high.

Evaporation of water

It is obvious that the nearer the temperature of the environment comes to that of the blood the smaller will be the amount of heat which can be lost by radiation and convection. At an air temperature of about 98.6°F. heat loss by these means must cease. At higher air temperatures than this, the body, were no other means of cooling available, would actually gain heat. Through the secretion and evaporation of sweat and the exhalation of water vapor (expired air is practically saturated with moisture) large quantities of heat are lost to the body. Its temperature can, for this reason, be maintained constant when the atmosphere (dry) has a temperature about 150°F. above that of the blood (see p. 626). The heat absorbed in the evaporation of 1 cc. of sweat amounts to 0.59 Calorie. Even at ordinary room temperatures when there is no obvious perspiration the heat lost through evaporation from the lungs and skin amounts to from 22 to 27 per cent of the total heat loss. At higher temperatures the increase in the proportion of heat lost by evaporation of water as compared with that lost by radiation and convection is shown in figure 245. It will be seen that evaporation plays little part in heat regulation until the air temperature reaches between 28° and 30°C., the heat loss by this means remaining nearly constant below this level but increasing rapidly

¹ The wave-length of the infra-red rays emitted by skin at usual temperature (34°C.) is 9440 mμ.

FIG. 244. Effects of cool (20°C.) bath upon dog with and without nervous heat regulation. Upper two curves, normal dog; lower two curves, dog after section of sixth cervical cord segment; continuous lines temperature; broken lines, blood solids. Note that normal dog keeps its temperature from falling by means of blood concentration. Dog with sectioned cord is poikilothermic because blood-concentrating mechanism has broken down. (After Barbour.)

umidity of the external air has little effect upon heat loss through convection. Probably the most important factor influencing heat loss by this means is air movement. A breeze or wind greatly increases heat loss by convection up to a wind velocity of around 70 miles an hour. A rise in wind velocity above this has little further effect.

More than half the total heat loss is brought about through radiation (p. 623). The human skin (of whatever color) is an almost perfect "black body radiator." That is to say, it radiates

above it. At a temperature above 35°C. evaporation accounts for all or nearly all the heat lost from the body.

It is to be remembered that evaporation from the body surface occurs quite independently of sweat secretion, for the skin is not entirely impervious to water; fluid extravasated from the cutaneous capillaries seeps into the epidermis. It has been shown for persons in whom sweat glands were absent from birth that some 18 grams of water per square meter of body surface may be lost hourly by evaporation. This is about the same as that of

inversely by the degree to which the atmosphere is already saturated with moisture, i.e., by its relative humidity.² Sweat which is not evaporated but simply drips from the skin, of course does not increase heat loss. For this reason the sweating mechanism for the elimination of heat is badly crippled when the relative humidity is high.³ We are all familiar with the fact that one feels hotter and suffers more discomfort when the atmosphere is hot, and humid ("muggy" or "sticky") than when it is simply hot and dry. A man can maintain a normal temperature in an atmosphere of from 240° to 260°F. provided the air is perfectly dry; the ability to sweat profusely is sustained by large draughts of water and evaporation is facilitated by stripping the greater part of the body's surface. This temperature will actually grill a beefsteak. On the other hand, a damp atmosphere with a temperature of 120°F. causes the body temperature to rise rapidly, and cannot be endured for more than a few minutes. Evaporation and consequently heat loss by this means is greatly hastened by air movement. The layer of air near y saturated with water vapor lying next the skin is thus replaced by drier air.

SWEATING

Sweat is a weak solution of sodium chloride in water together with urea and small quantities of potassium and lactic acid. It has a specific gravity of from 1.002 to 1.003. Its pH as reported by different observers varies from 4.2 to 7.5. The percentage of sodium chloride varies between 0.2 and 0.5. Muscular exercise increases the salt concentration, which is also higher in sweat secreted by clothed than by naked skin. The quantity of non-protein nitrogen ordinarily excreted in the sweat, per day, is according to Benedict 0.071 gram; on the other hand, if the sweating is copious from 0.5 to 1.0 gram may be eliminated per hour. The actual concentration of nitrogen in the sweat falls, however, when sweating becomes profuse, whereas the concentrations of sodium chloride and

FIG. 245. Rubner's chart showing the manner of heat loss in the dog at different room temperatures. Stippled area, heat loss in calories through evaporation of water; cross-hatched area, heat loss in calories through radiation and convection. The distance between opposite points on the curved lines represents the total heat production at a particular temperature. (Redrawn and slightly modified from Lusk.)

a normal man under ordinary conditions, and represents a total daily heat loss of about 450 Calories for a body of average size (surface area 1.8 square meters).

The respirations are increased by a rise in air temperature or by a greater heat production; the heat loss through warming the inspired air and the vaporization of water from the lungs is thereby increased. Hyperpnea (panting) is the chief means possessed by the dog (in which sweating is practically confined to the foot-pads) for increasing the vaporization of water and combating a rise in body temperature.

The rate of the evaporation of water is influenced

² It is dependent essentially upon the difference in the vapor pressure at the skin and of the surrounding air.

³ The relative humidity is defined as the ratio of the weight of water vapor contained in a given volume of air to the weight which the same volume of air would contain when saturated. The quantity of water vapor which air can hold when saturated increases with the temperature. The relative humidity is expressed as a percentage. Thus, if a sample of air at a certain temperature contains 20 per cent of the water vapor which it is possible for it to contain at that temperature, it is 20 per cent saturated, and so has a relative humidity of 20 per cent.

potassium rise. Therefore, if strenuous work is performed for a long period in a high temperature, and large quantities of water are drunk, depletion of the body's supplies of chloride and a lowered concentration of this element in blood and tissue fluids result.⁴ Severe cramps occur in the muscles of the limbs and abdominal wall ("stoker's" or "miner's cramp"). In order to prevent these effects it is recommended that the thirst be quenched with a weak salt solution (0.2 per cent) instead of with water.

The control of sweat secretion

The sweat glands are under the control of the sympathetic nervous system. These glands are, however, anomalous in their responses to sympathetic and parasympathetic drugs, in that they are stimulated by muscarine, pilocarpine and acetylcholine, and inhibited by atropine (p. 948). According to Coon and Rothman, the action of acetylcholine is twofold,—stimulation of the glands directly through a nicotine-like action and through the initiation of axon reflexes (muscarine-like action). In man and most animals, they are not excited by adrenaline nor paralyzed by ergotoxine. The usual stimulus to sweat secretion is a rise in blood temperature which exerts its effect in two ways—directly upon the nervous centers, which is of more importance, and reflexly by stimulation of heat receptors in the skin. The sweat response to a rise in temperature is abolished by sectioning the nerves to a part and is therefore not due to direct stimulation of the glands. That a rise in temperature of the centers alone will induce the secretion of sweat has been shown by heating the carotid blood in the cat (whose sweat glands are confined to the paw pads); sweating then occurs though the paws themselves remain cool. The centers may also be stimulated in man by the injection of pituitrin into the lateral ventricle (p. 735). In the initial stages of muscular exercise sweating is apparently due to the discharge of impulses from the motor cortex. It occurs before there is any change in rectal temperature. Later on, the effect of a rise in body temperature comes into play. In a man (indoor clothing) at rest, visible sweating usually commences at an air temperature between 80° and 90°F. Sweating may be induced by the experimental stimulation of regions of the diencephalon (hypothalamus, p. 883). Spinal centers also exist, since after complete transection of the cord reflex sweating occurs in the

parts of the body below the level of the lesion (p. 871). Destruction of the sympathetic nerve supply to a part completely abolishes the sweating response to a rise in temperature. The sweat glands, however, still respond to pilocarpine. This drug, which has been employed in the past for the purpose of demarcating areas deprived of their sympathetic supply, is of no diagnostic value, for it acts peripherally, i.e., directly upon the gland cells. Sweating is not dependent upon the circulation for it occurs after occlusion of the vessels and can even be induced by stimulation of the nerves in an amputated limb. Though usually associated with cutaneous vasodilation it may occur with constricted vessels—*cold sweat*. This is usually the result of psychic influences, e.g., nervousness, fear, fatigue or mental work. The sweating occurs in these instances most noticeably on the forehead, the palms of the hands and the soles of the feet. In many persons reflex sweating, confined to the face, is induced by eating spicy food (gustatory sweating). Faradic stimulation of the human skin over the forearm induces local sweating due apparently to direct stimulation of the glands, for it occurs after section and degeneration of the nerve supply.

The few observations that have been made upon the secretion pressure of sweat indicate that it is high—250 mm. of mercury or more. Sweat is therefore a true secretion and not simply a filtrate. The secretion rate may be enormous, amounting to a liter or more per hour, and may be increased some 80 times over the normal by immersing the body in a bath at 108°F. At ordinary room temperatures the sweat evaporates as quickly as formed, so that there is no apparent secretion. The loss of sweat in this way together with the evaporation of water from the lungs and from the surface of the body independently of the sweat glands is called *insensible perspiration*. Its amount varies directly with the basal metabolism.

THE CHEMICAL REGULATION OF BODY TEMPERATURE—HEAT PRODUCTION

The several factors which stimulate the chemical processes of the body and so increase the heat production (metabolism) have been dealt with in Chapter XLVI. There remains to be given an account of the manner in which chemical and physical factors interact to maintain a constant body temperature.

A low environmental temperature is a potent influence in stimulating heat production. At air temperatures below about 28°C. the body (nude) loses heat rapidly. Within the temperature

⁴ A miner performing heavy work may lose a quart of sweat per hour.

range between 28° and 30° or 31°C. the naked male body is able quite easily to maintain the balance between heat loss and heat production. There is neither sweating nor shivering and a male subject feels comfortable. This range of temperature is therefore called the *comfort zone*. For reasons given below the comfort zone is broader (27° to 32° or 33°C.) for women. The external temperature below which heat production must be increased in order to maintain a normal body temperature is sometimes called the *critical temperature*.

Below the critical temperature radiation of heat from the body increases progressively with falling air temperature, but heat loss by conduction and vaporization shows little change. The naked body at a temperature below the critical level loses more heat than it can produce in the basal state, and at about 23°C., or when the body temperature has dropped by about 0.6°C., a chill (shivering) occurs. Heat production is thus increased in an effort to raise the body temperature to the normal level. In the human subject heat production is not increased until the onset of the chill and in men under basal conditions the metabolism remains constant within the range of air temperature from 35° to 22° or 23°C.⁵ It has been shown by Hardy and DuBois that this is not true for women. They show a *reduced* heat production of from 14 to 20 per cent at temperatures between 30° and 32°C. Also, owing to the greater insulation afforded by the thicker layer of subcutaneous fat the heat loss of the female body in a cold environment is some 10 per cent less than that of men. Thus women have a more efficient thermo-regulating mechanism than have men, being better able, contrary to general belief, to resist cold and also to be more comfortable at higher temperatures. The temperature of the female skin is more than 1.5°C. higher than that of a man's skin at the higher environmental temperatures; a woman also sweats less. In a cold environment a woman's skin is about 1.0° cooler than a man's since the conduction of heat from deeper parts is impeded by the thick mantle of subcutaneous fat.

The critical temperature and the temperature of comfort will vary of course with the amount and nature of the clothing. The cooling effect of water is some 14 times greater than that of air—a cold

bath at 40°F. increasing the heat production some 12 times above the resting level for the first minutes or so⁶ (L. Hill and Campbell); after that the heat-producing mechanism becomes depressed and the body temperature falls.

It will be seen from figure 246 that heat loss increases both above and below the critical temperature. At the lower temperatures heat is lost mainly by radiation and convection, at the high temperatures mainly by vaporization. It will also be noticed that at the lower temperatures the skin temperatures follow a straight line, but that the curve commences to flatten out at about 30°C. This is attributed to dilatation of the c

FIG. 246. Showing effect of a rising air temperature on rectal and skin temperatures, heat loss, and vaporization. (Modified from DuBois.)

taneous vessels and the flooding of the skin with blood.

The muscular tissues (particularly of the extremities) and the liver wherein numerous chemical reactions are carried out, are the main sources of the body's heat. The rise in metabolism which results from a fall in atmospheric temperature is effected through an increase in tone of the skeletal muscles and in some instances by fine involuntary contractions, e.g., shivering and chattering of the teeth. Contractions of the smooth muscle of the skin, giving rise to "goose flesh" also contribute. In some mammals and in birds, the contraction of

⁵ Rubner believed that chemical regulation at low environmental temperature involved some factor other than an obvious increase of muscular activity. In animals, adrenaline is liberated during short exposures to cold and stimulation of the thyroid by prolonged periods has been demonstrated (p. 630), but chemical regulation of this nature has not been shown for man.

⁶ In cold-blooded animals, which possess no chemical regulation, the metabolism as measured by the carbon dioxide output falls with the environmental temperature.

the cutaneous muscles also curtails heat loss through ruffling of the hair or feathers. When the skeletal muscles are paralyzed by curare, the animal loses the power to maintain a normal body temperature in a cold environment. Its physical mechanisms of control are, however, intact so that it can resist high air temperatures. Isolation of the muscles from control by section of the cord in the lower cervical region (C.6) also abolishes the chemical regulation. This operation abolishes physical regulation as well, for, as already mentioned, concentration of the blood does not occur and the body temperature falls when the animal is exposed to a low temperature (fig. 244). The rise in body temperature mentioned on p. 623 as occurring in strenuous muscular effort is apparently due, not to any failure of the heat-dissipating mechanisms, but to the "thermostatic" control being set at a higher level, for the temperature

TABLE 63

ATMOSPHERIC TEMPERATURE	HEAT PRODUCTION CALORIES PER KILOGRAM BODY WEIGHT		
	Starved	550 grams of meat fed	Increase
°C.			
4.2	128	133	4
14.5	101	111	9
22.1	71	101	43
30.7	62	117	89

rise is the same whether the exercise is performed at an air temperature of 3° or of 23°C.

Food, especially protein through its *specific dynamic action*, is an important factor in the chemical regulation of body temperature. At high environmental temperatures the specific dynamic action of food acts counter to the physical mechanisms which hasten heat loss. For this reason a low protein diet is more suitable in hot weather. At very low atmospheric temperatures, on the contrary, the specific dynamic effect of food is almost completely masked, since it simply replaces the environmental effect (cold) upon heat production. That is to say, the neuromuscular mechanisms called into play to increase heat production at low temperature are less necessary since the food itself stimulates the body cells to a higher level of metabolism. Protein food in cold climates is therefore a valuable aid to the chemical regulation of body temperature.

The effect of protein ingestion upon the heat production of a dog at different temperatures is shown in table 63 (Lusk).

CONTROLLING CENTERS

Section of the neuraxis through the mid-brain at the level of the superior colliculi or at any level posterior to this and anterior to the lower cervical cord renders an animal poikilothermic (fig. 247). Section of the cord in the upper thoracic region, i.e., above the level of the outflow of the greater part of the sympathetic fibers, abolishes physical heat regulation but leaves chemical regulation to a large extent intact, since the muscles of the fore part of the body remain in communication with the central nervous system. The effect of section through the brain stem indicates that the main center or centers controlling heat regulation must lie anterior to the superior colliculi. Removal of the cerebral cortex, thalamus or corpus striatum does not destroy the controlling mechanisms so long as the hypothalamus remains intact. Destruction of this region alone, however, was found by Keller and Hare to abolish the ability to maintain a normal body temperature upon exposure to cold. The heat-dissipating mechanisms remained intact and were, in fact, released from restraint by the hypothalamic lesion, as evidenced by pronounced panting and vasodilatation.

The thermoregulatory centers have been located more precisely by Ranson and his associates. From the results of their experiments upon cats and monkeys they place the centers controlling heat loss (sweating and panting) in the preoptic and supraoptic regions between the anterior commissure and the optic chiasma. Heating this area causes sweating and panting or rapid breathing, and a fall in body temperature. Destructive lesions in this situation are followed by hyperthermia when the animal is exposed to a degree of heat that would cause little effect upon the body temperature of a normal animal. Sweating or panting does not occur though the temperature rises to over 106°F. Such lesions have little effect upon the animal's ability to resist cold. The centers controlling heat production and heat conservation, i.e., the mechanism whereby an animal is enabled to maintain a normal body temperature when exposed to cold, is situated, according to these investigators, in the caudal part of the lateral hypothalamus; it appears to be identical with the sympathetic center. The existence of a center for shivering (heat production) in the hypothalamus is suggested by the fact that under certain circumstances shivering in animals is accompanied by some of the manifestations of "sham rage" (Barcroft and Izquierdo). That the posterior part

of the hypothalamus contains the main shivering center is indicated by the experimental results of Kellar and his associates and of Ranson and his colleagues who found that, in cats, shivering was abolished by a destructive lesion in this situation. The efferent pathway for shivering is unknown, but an observation upon a patient in whom both spinothalamic tracts had been sectioned and who did not shiver when the legs were immersed in cold water, suggests that the impulses descend the cord

uncommonly with hyperthermia; hypothermia, on the other hand, may accompany lesions involving the posterior part of the hypothalamus.

As mentioned on page 624 the main heat-regulating centers are apparently influenced in various ways—reflexly from the skin and by the temperature of the blood flowing through them.

The posterior hypothalamic center apparently exerts its controlling influence upon temperature through the transmission of sympathetic impulses to the cutaneous vessels, sweat glands and peripheral motor muscles; removal of the sympathetic innervation renders an animal unduly susceptible to cold (p. 945).

THE ENDOCRINES IN THERMOREGULATION

The thyroid and adrenals also play their probably important roles in the regulation of body temperature. The calorogenic effects of the secretions of these glands are well known (pp. 682, 683). Cannon observed that exposure to cold caused an increase in the rate of the denervated heart (p. 690). It has also been reported that the serum taken from an animal exposed to cold raises the metabolism of a second animal into which it is injected. If the first animal has been thyroidectomized, the effect upon the metabolism of the second is not observed. The adrenal secretion exerts a calorogenic effect which is immediate and of short duration. Its liberation follows short periods of exposure to cold. But owing to the delayed action of the thyroid hormone and the persistence of its effects it does not seem possible that the thyroid could play any part in increasing heat production unless the cold stimulus were continued over a long period. Rats exposed over a period of weeks to low temperatures (7.8 to 12.2°C) showed thyroid hyperplasia and a rise in metabolic rate of as much as 16 per cent which was not reached, however, until the lapse of from 2 to 3 weeks. Thyroidectomized rats, on the contrary, show little rise in metabolic rate under the same conditions. The experiments of Uotila point to the pituitary as being responsible for the thyroid response to cold, for hypophysectomy causes thyroid atrophy as usual, though the animals are exposed to a low temperature for long periods. It may be mentioned in this connection that the temperature tends to be subnormal in suprarenalectomized or thyroidectomized animals, in Addison's disease, and in cretinism.

DISTURBANCES OF HEAT REGULATION

Since the body temperature represents the balance struck between heat production and heat loss

FIG. 247. Diagram to illustrate the nervous control of the heat-regulating mechanisms. (Modified from Martin.)

by these paths. The impulses are not transmitted by sympathetic nerves, since shivering occurs in sympathectomized parts. Shivering is reduced or abolished by certain drugs, especially calcium chloride and aminopyrine which act most probably upon the shivering center.

From observations of patients with intracranial lesions involving the base of the brain, it seems most likely that in man the centers are situated as described by Ranson and his associates for animals. Lesions in the supraoptic region are associated not

a disturbance in the value of one of these factors in relation to the other obviously will be followed by a temperature change.

Temporary rises in temperature may occur in health as a result of hot baths which prevent heat loss through conduction, radiation and the evaporation of sweat, as well as by actually adding heat to the body; or during violent muscular exercise which increases heat production. Owing to the high efficiency of the chemical mechanism of control, a fall in the temperature of a normal person is much more difficult to produce than is a rise.

The heat regulating mechanisms are depressed by anesthetics, during sleep and hypnosis and by general bodily fatigue.

HEAT STROKE

Heat stroke is due to exhaustion or inadequacy of the heat dissipating mechanisms and occurs as a result of exposure to a hot humid atmosphere; the hyperthermia may seriously damage the nervous tissues and prove fatal. *Sunstroke* is simply a form of heat stroke; but in addition to the reduction in heat loss as a result of the high atmospheric temperature there is an absorption of solar radiant energy. This may cause a local elevation of temperature above that of the body generally in regions such as the brain or cervical cord, which are unprotected from the heating effects of the sun's rays. Powerful sunshine itself, however, will not cause sunstroke provided heat dissipation is adequate to keep pace with heat production, i.e., when the air is dry and cool and strenuous exercise is not undertaken. The most valuable measures for the prevention of these effects of overheating are, a light diet, avoidance of exertion, plenty of water to drink, loose airy clothing or stripping to the waist, electric fans, cold douches and the protection of the head and nape of the neck from the direct rays of the sun.

FEVER (PYREXIA)

Types of fever:

- (1) *Infectious fever*, e.g., sepsis, typhoid, pneumonia, etc.
- (2) *Surgical fever* which arises after an extensive aseptic operation and is apparently due to toxic substances liberated by the injured tissues.
- (3) *Neurogenic fever* from injuries to nervous centers, especially lesions in the neighborhood of the third ventricle, internal capsule, medulla or upper part of spinal cord.
- (4) *Fever of dehydration* due to a reduction of blood-water (anhydremia, p. 19). This is particularly likely to occur in young children.
- (5) *Fever produced by drugs and other chemical substances.*

Intravenous injections of concentrated *solutions of glucose* or *salt* induce fever by causing anhydremia (p. 19). Drastic *cathartics*, by drawing water from the blood into the bowel, may cause fever in a similar manner. *Caffeine* and *cocaine* in large doses induce fever by increasing muscular tone (greater heat production) and by causing blood concentration (reduced heat loss, see also (p. 624). *Hemoglobin* solutions when injected into the blood stream exert a pyretic action; the hemolysis resulting from the intravenous injection of distilled water acts similarly. The manner in which the fever is produced is unknown. *Beta-tetrahydronaphthylamine* injected subcutaneously raises the temperature by its action upon the central and peripheral sympathetic mechanisms, causing cutaneous vasoconstriction and consequently a greater conservation of heat. It also, through its action upon the muscles, causes increased heat production. The adrenal medulla is also probably stimulated by this drug and the outpouring of adrenaline may be an added factor in the temperature rise. *Ergotoxine* causes a rise in temperature in some animals (cat), presumably through a direct action upon the heat centers. *Dinitrophenol*, a drug sometimes used in the treatment of obesity (p. 611), and injections of *foreign protein* also raise the body temperature. Dinitrophenol acts by stimulating oxidative processes in the tissues. *Adrenaline* and *thyroxine* in large doses may also, through their stimulating effect upon the metabolism, cause a rise in temperature.

Infectious fevers

At the *onset* of an acute infectious fever the heat balance is upset by a reduction in heat loss as a result of vasoconstriction and a reduction in blood volume, combined with an increase in heat production. That is, those mechanisms which in health prevent a fall in temperature when the body is exposed to cold, are called into play by a stimulus within the body itself, namely, the toxin of the infecting organism.

The reduced heat loss by radiation and convection in the early stages of the fever is evident in the cold, pale or slightly cyanosed skin. At this time, though the body temperature may be higher than at any subsequent stage, the patient often experiences sensations of extreme cold (chills) with shivering, chattering of the teeth and "goose flesh." In health, the comfortable feeling of warmth depends not upon the temperature of the deeper structures but upon the stimulation of the cutaneous sense organs (corpuncles of Ruffini) by the warm blood coursing through the superficial vessels. The chills are due to the spasm of these vessels and the exclusion from them of the warm blood of deeper regions. The fall in skin

temperature acts as a stimulus which calls into play the mechanism of chemical regulation; shivering, which consists of fine contractions of the muscles, occurs; muscle tone increases; and the smooth muscle of the skin contracts. The increased heat production thereby induced is an additional factor in the elevation of the body temperature. Later, when the body temperature reaches a certain height, a heat response is evoked from the centers, the vessels are released from spasm, the blood flow through the skin increases, the body surface becomes flushed, and the patient feels intensely hot. The balance between heat loss and heat production is again restored but set at a higher level than in health. The body's "thermostat" is turned up a point or so.

DuBois in an experiment upon a normal man and a malarial fever patient demonstrated the reduced heat elimination which occurs during the chill. The normal subject imitated as closely as possible for a period of 34 minutes the shivering of the patient and thereby increased his heat production by nearly 200 per cent. Most of the extra heat was eliminated as it was produced, the body temperature showing only a slight rise. In the malarial patient, on the contrary, in whom the heat production during the chill was increased to about the same degree, all the extra heat was retained.⁷ The heat retention caused a rise of 2°C. in body temperature. After the chill the heat elimination rose and the temperature fell.

The *continued* fever which usually follows the initial chill of an infectious disease, or which develops in other instances without this preliminary, is due essentially to the raised threshold for heat loss. There is, of course, increased heat production but this is mainly secondary—the velocity of the oxidative processes of the tissues being increased by the rise in temperature induced by the diminished heat elimination.⁸ That the latter rather than increased heat production is the principal factor in the elevated temperature is indicated by the fact that in fever a temperature of 104°F. (40°C.) is accompanied by an increased heat pro-

duction of only about 35 per cent whereas in health the heat production must be increased several fold (as in muscular exercise) in order to raise the body temperature even transiently to this extent. Although the metabolism may be raised 40 per cent or so in an animal by protein feeding (see specific dynamometer action, p. 554) without the occurrence of a temperature rise. Furthermore, the increased metabolism in ordinary fevers occurs simultaneously with the temperature rise. If the latter were the result rather than the cause of the former, it should be possible to demonstrate by indirect calorimetry a period of increased metabolism *preceding* the rise in temperature; this, however, does not occur.

With the termination of the fever, sweating (or at least moistening and cooling of the skin) occurs, the heat-balance is restored to its normal level, the heat which had been retained is eliminated either

FIG. 248. Shows relationship between basal metabolism and body temperature in fever. Results in six different fevers grouped in one chart. The continued line shows the average metabolism, the interrupted lines the metabolism 10 per cent above and 10 per cent below the average respectively. (After DuBois.)

gradually or with comparative abruptness (crisis) and the temperature falls.

In infectious fevers the bacterial toxins act either directly or indirectly upon the heat center or center. In decerebrate animals or in those in which the cord has been divided in the lower cervical or upper thoracic regions the injection of infective agents does not cause fever nor is a rise in temperature so produced in animals possessing no heat regulating mechanisms. Balfour suggests that the first effect of the toxin is not directly upon the heat regulating centers but upon the peripheral tissues. In these, it is conceived, chemical changes are initiated which result in the withdrawal of water from the blood. The reduced volume of circulating fluid causes blood to be drained from the skin vessels and thereby calls forth a reflex cold response from the heat regulating mechanisms. That is, the nervous centers respond by causing vascular spasm, shivering and a further increase in blood concentration. The mechanism involved at the onset of fever is there-

⁷ The water equivalent of the human body is 0.83 times its weight in kilograms (W) per °C. rise in temperature (t°C.); the retained heat may therefore be calculated from the formula $t^{\circ} \times W \times 0.83$.

⁸ The increase in metabolism with rise in temperature follows van't Hoff's law which states that the velocity of chemical reactions increases from 2 to 3 times for a temperature rise of 10°C. That is, the *temperature coefficient* is between 2 and 3. The basal metabolism actually increases about 13 per cent for each degree Centigrade rise in body temperature or 7 per cent for each degree Fahrenheit (fig. 248).

fore comparable to that which produces a rise in temperature of a healthy man after a cold plunge. The cold water causes, through vasoconstriction, diminished heat dissipation and through shivering, increased heat production. The body temperature may rise for a few minutes. After the first effect of the plunge the vessels are released from spasm, the stored heat is eliminated, the surface of the body glows and a feeling of comfortable warmth is experienced. This constitutes the "healthy reaction" of a cold shower and may be compared to the period following the fever chill, except that in the latter case the heat balance is set at an abnormally high level. The factors causing the continuance of the fever, on the other hand, are similar to those which cause a rise in temperature during the immersion of the body in a hot bath. Heat dissipation is greatly reduced and heat production is increased purely as a result of the elevation in temperature of the tissue cells.

Special metabolism in fever

Water and salt. At the onset of a high fever the blood volume, as already mentioned, is reduced, the reduction being due to the loss of water (anhydremia). Later the volume of the blood tends to increase (hydremlia) as a result of the shift of water from the tissues to the vessels. During the course of the fever the urine volume is markedly reduced, but is increased above the normal when the temperature falls. The vaporization of water is greatly increased in fever, owing chiefly to the high temperature of the skin and lungs.

There occurs a retention of chloride which apparently is deposited in the tissues, the chloride concentration of the blood being normal or below normal. The urinary chlorides in most fevers are greatly reduced. At the termination of the fever the retained water and chloride are eliminated by diuresis and sweating. Chloride retention is especially pronounced in pneumonia.

Protein. The excretion of nitrogen in the urine is greatly increased in most infectious fevers. This is furnished by body protein, the protein minimum, i.e., the "wear and tear" quota of protein metabolism (p. 554), being much higher than normal. In very severe infections from 300 to 400 grams of body protein may be destroyed daily. It has been found impossible to maintain the fever patient in nitrogen equilibrium (p. 552) by giving liver allowances of protein combined with supplies of carbohydrate which under ordinary circumstances would be considered quite adequate for energy purposes. It has, therefore, been held that the toxins of the disease were responsible for the protein destruction, the so-called "*toxic destruction*"

of protein. It has been shown, however, by Shaffer and Coleman that if a diet be given possessing a caloric value 50 to 110 per cent in excess of the patient's requirements, as actually determined by calorimetry, and containing a liberal supply of protein (160 to 200 grams) nitrogen equilibrium *can* be established. The high protein catabolism which has been observed in fever patients on the usual diet is therefore thought to have been due in large measure to the fact that the caloric intake was far below the requirements, which owing to the higher metabolism in fever are considerably greater than has been supposed. In other words, a fever patient upon a diet which has been considered adequate in the past is actually in a half-starved state, and is, in consequence, forced to consume his own tissues.

Nevertheless, even on a high caloric diet composed of carbohydrate and a small quantity of fat, the nitrogen excretion still remains well above that of a normal person. Moreover, a protein allowance equivalent to that of a healthy man together with carbohydrate somewhat more than sufficient to cover the calculated calorie requirements of the febrile state will not maintain nitrogen equilibrium. As just mentioned, the calorie allowance must in some instances be double the heat production of the patient. It therefore appears that the toxic process itself must be responsible in part for the increase in protein metabolism. Creatinine, uric acid, purine bases and phosphates also appear in the urine in increased amounts—further evidence of a destruction of body protein. The manner in which the "toxic" effect is produced is not known, but since it can be abolished by an appropriate diet it is evidently not due to the bacterial products acting directly—simply as protoplasmic poisons. Nor does it appear that the protein destruction is merely the result of the high temperature, for, raising the temperature of a normal person to 104°F. by immersion in a hot bath does not increase the nitrogen excretion significantly.

It must be apparent from the foregoing remarks that in order to reduce the waste of body tissue in fever a liberal diet should be given, provided such is not contraindicated by some special feature of the disease. The old adage "feed a fever" holds true. Since the very high protein diet required for the establishment of nitrogen equilibrium in the fever patient has its disadvantages, one must usually be satisfied with reducing the waste of body protein rather than aiming to abolish it. Special attention, therefore, is directed toward furnishing

an abundance of protein-sparing food (p. 553), namely carbohydrate, and thus avoiding excessive quantities of protein. The more abundant diet causes a negligible increase in heat production and no elevation of the temperature.

Fats and carbohydrates. The metabolism of body fat or carbohydrate shows no definite abnormality in fever. In patients upon a low food intake body fat and glycogen are utilized as fuel. Acidosis results from the incomplete combustion of fat only if the available carbohydrate is inadequate in amount.

THE ACTION OF ANTIPYRETIC (FEVER-REDUCING) DRUGS. A list of chemical substances which are capable of inducing a rise in body temperature has been given on page 631. Other drugs, e.g., antipyrine, aspirin, salicylates, quinine, etc. though they exert little effect upon the normal temperature, lower the temperature in fever by increasing heat elimination. According to Barbour they bring about this effect through drawing water from the tissues into the vessels and thus increasing the volume of fluid in the body's heat radiating system. They appear to exert little effect upon heat production. The effect upon the blood volume is possibly brought about indirectly. All these substances raise the blood sugar; the greater sugar concentration may then through osmotic forces attract water into the vascular system.

Certain other drugs, e.g., morphine, general anesthetics and alcohol, tend to depress the *normal* body temperature chiefly through blood dilution and dilatation of superficial vessels. In the case of morphine and general anesthetics a direct depressant action upon the heat centers is also indicated.

THE VALUE OF FEVER. Fever is frequently the herald of serious disease; nevertheless, unless of high degree and on this account endangering the functions of vital tissues, it should not be looked upon as a reaction detrimental in itself. On the contrary, there is every indication that its occurrence is an important aid to the body in its combat with the disease. The rôle which fever plays in the defensive process is, however, unknown. It was been suggested that the formation of antibodies can be elaborated only at higher

temperatures. It is well known, for instance, that infections which overwhelm the individual the temperature reaction is depressed. In support of the belief that moderate fever is not injurious in itself but actually beneficial the following observations upon animals may be cited. (a) The body temperature of rabbits has been maintained by the application of external heat at a level of over 105°F. for weeks at a time without ill effects. (b) In animals infected with certain microorganisms the disease runs a milder course when the temperature is raised (to 40°C.) artificially. (c) It has been reported that with moderate overheating the formation of various antibodies is increased, but at higher temperatures the process, apparently, is depressed. The immunity of fowl to the ordinary pyogenic infections is ascribed to their higher body temperature which is inimical to the growth of pus-forming bacteria. (d) Fevers induced artificially by means of foreign proteins or injections of malarial blood are used as therapeutic agents in arthritis and certain chronic nervous diseases. Short wave diathermy has been employed with success in the treatment of certain infections—the high temperature produced in the tissues exerting a lethal action upon the microorganisms.

REFRIGERATION—CRYOTHERAPY. In chronic incurable disease e.g., carcinoma, refrigeration of the patient is sometimes resorted to for the relief of severe intractable pain. Ice is packed around the patient or some other means is used to reduce the temperature of the body to between 80° or 90°F. This temperature is maintained for hours or days. The patient becomes unconscious, passing into a state of "suspended animation," which in many respects is comparable to that of an animal during hibernation. The heart rate and respirations are slowed and the radial pulse may be imperceptible. The blood pressure falls below the level at which it can be measured, urine production is greatly diminished or suppressed and gastrointestinal activity is minimal. The blood volume is reduced as a result of the loss of water (hemoconcentration or anhydremia). The metabolism, in accordance with van't Hoff's law is reduced by from 20 to 50 per cent. The respiratory quotient is probably not greatly lowered, but in hibernating animals, in which the metabolic processes are altered qualitatively as well as quantitatively, it is around 0.60.

CHAPTER LV

THE VITAMINS

INTRODUCTION. NOMENCLATURE

In 1911 Casimir Funk, as a result of his investigations into the cause of beri-beri obtained a crystalline substance from rice polishings which was capable of preventing or curing this nervous disease. He named the substance *vitamine* in view of its quite evident importance to life, believing, though erroneously, that it was an amine. Subsequently a number of similar substances playing an essential rôle in nutrition were discovered for which the general term *vitamin* was agreed upon, the individual vitamins being designated by letters of the alphabet. In the state of knowledge at the time such a method of designation had the advantage of being non-committal as to the chemical nature and other properties of this group of substances. The following is a classification of the known vitamins and their chief physiological effects:

Vitamin A (antixerophthalmic)

Vitamin B complex	<div style="display: inline-block; vertical-align: middle;"> <div style="display: inline-block; vertical-align: middle;"> thiamin (B₁) riboflavin (B₂) nicotinic acid pyridoxin (B₆) pantothenic acid inositol biotin para-aminobenzoic acid choline </div> </div>
-------------------	---

Vitamin C (antiscorbutic)

Vitamin D (antirachitic)

Vitamin E (antisterility)

Vitamin K (antihemorrhagic)

Vitamin P (capillary permeability)

Vitamins A, D, E and K are fat-soluble. The others, namely, those of the B complex, C and P are water-soluble. Riboflavine is also called vitamin B₂ and sometimes vitamin G (see p. 642).

VITAMIN A (ANTIXEROPHTHALMIC)

This was discovered as a result of the investigations of Hopkins in England and of Osborne and Mendel, and McCollum and Davis in America.

Sources

The chief sources of vitamin A are mammalian and fish liver, egg yolk, butter, cream and a number

of vegetable foods. Cod-liver oil has a very high but halibut oil a much higher content in this vitamin. Vegetable oils with the exception of corn oil and red palm oil contain little or none. Lard and beef fat are as a rule poor sources of this vitamin; their vitamin A content varies considerably, however, with the animal's diet. Cereals, with the exception of maize, are relatively poor in vitamin A. In plant tissues there is a definite relationship between their green or yellow coloring and their vitamin A activity. Thus, the sweet (yellow) potato is a good source, whereas the ordinary potato possesses very little or none; the outer green leaves of lettuce contain some 30 times more of the vitamin than do the inner white leaves. Carrots, yellow maize, escarole, spinach, cress, string beans, green peas, pumpkin, bananas and cantaloupe are rich in the vitamin whereas in white corn, celery, cauliflower, white turnips, cabbages, radishes and other colorless vegetables it is present in small amounts or entirely lacking. The *vitamin A requirement* for man is from 4000 to 6000 international units (p. 662).

Chemical properties and history in the body

Vitamin A is soluble in fats and fat solvents. It is present in the unsaponifiable fraction of the fat. It is resistant to heat in the absence of air but is readily destroyed by oxidation at all temperatures. Though colorless itself it gives a blue color with antimony trichloride in the presence of oxygen. In oily solution vitamin A, or its esters in alcoholic solution, show a green fluorescence when exposed to ultraviolet light. This property has been employed to demonstrate microscopically its distribution in the body tissues, e.g., Kupffer cells, retina, adrenal cortex, testes and corpus luteum. It is also seen in actively secreting mammary glands and in tumor tissue. The fluorescence gradually fades, presumably as a result of the destruction of the vitamin by the ultraviolet rays.

Vitamin A is an unsaturated alcohol with the empirical formula C₂₀H₃₀O and is derived from the reddish yellow pigment *beta-carotene*—C₄₀H₅₆—one molecule of the latter being split into two molecules of the vitamin, thus; C₄₀H₅₆ + 2H₂O → 2C₂₀H₃₀O.¹

¹ Carotinoid pigments of vegetable food are also largely responsible for the fat pigment of animals.

Vitamin A has been isolated in crystalline form and recently synthesized. Euler, in 1928, showed that pure carotene from carrots was capable of replacing vitamin A in the diet. Moore later found that feeding rats with pure carotene caused a great increase in the vitamin A contents of their livers. It is therefore concluded that carotenes, of which there are three forms, *alpha*, *beta* and *gamma*, and possibly other plant pigments (e.g., cryptoxanthin) are the precursors of vitamin A. Beta-carotene is of chief importance; the alpha form gives rise to one molecule only of vitamin A. When taken in the food, the carotene or *provitamin*, as it is called, is converted into vitamin A in the liver where it is also stored (probably in the Kupffer cells). The conversion is relatively slow and not complete; probably not more than from 30 to 50 per cent of ingested carotene is converted into the vitamin. Drummond and McWalter found an increase in the livers of rabbits eight days after the intravenous injection of carotene, but not sooner; incubation of carotene *in vitro* with liver tissue did not, however, result in the formation of vitamin A.

Vitamin A does not, apparently, exist as such in plants but only in the form of the provitamin.² Algae, diatoms and other marine plants synthesize the provitamin, and serve as food for small marine forms referred to in general as zooplankton, i.e., copepods, molluscs, etc. The zooplankton serve as food for various species of small fish (herring, whiting, young cod, etc.) which thus receive the necessary supplies of provitamin. The smaller fish upon which the larger fish such as cod and halibut feed provide these latter with vitamin A. Herbivorous animals obtain the provitamin from fodder (alfalfa is a particularly rich source). Dairy

foods rich in the provitamin or animal tissue which contain it preformed. The concentration of vitamin A in the liver of the new born infant is low for the placenta transmits little from the mother the concentration increases gradually during the first few weeks of life, the vitamin being supplied to the off-spring in the milk. The quantities of vitamin A and carotene in human milk are relatively high, and are highest in colostrum and early milk. Bile, though necessary for the absorption of carotene, is not required for the absorption of vitamin A. Absorption of both the vitamin and provitamin, on the other hand, is favored by the presence of fat or phospholipids, e.g., lecithin, in the intestine, whereas petrolatum has a definitely depressing effect, especially upon the absorption of carotene. The vitamin is found in the liver and intestinal tract, chiefly in the form of esters, which, before their absorption from the latter situation, are hydrolyzed by the lipases of the intestinal and pancreatic juices. During absorption the vitamin is found in the intestinal mucosa in the form of the alcohol.

In experiments upon rats Moore discovered an interesting synergic relationship of vitamin E with vitamin A. The administration of vitamin E increases the storage of vitamin A in the liver, prolongs the time required to exhaust the reserves and postpones the dental abnormalities due to vitamin A deficiency. Vitamin E probably exerts its effect by acting as an antioxidative agent in the gastro-intestinal tract. Rancid fats and unsaturated fatty acid esters (linolenates, linolates) have the opposite effect, tending to inactivate vitamin A through oxidation.

Vitamin A has been given the following structural formula by Karrer.

cattle convert it in part into the colorless vitamin A.³ This, as well as unchanged carotene is excreted in the milk. Man may therefore acquire a supply of this vitamin either by consuming plant

² Since the actual and only important effect of carotene after ingestion is that of vitamin A, it still remains the custom to speak of the vitamin A value of a food rather than of its carotene content.

³ The proportion of carotene converted, and so the color of the milk, varies in different breeds of cattle. It is evident that a pale-colored milk may have a vitamin A value as high as or higher than one more richly colored.

Below is a comparison of the properties of carotene and vitamin A.

Carotene	Vitamin A
Synthesized by plants	Stored by animals
Reddish-yellow in color	Almost colorless
Absorption band at 328 mμ absent	Absorption band at 328 mμ present
Greenish-blue color reaction with antimony trichloride giving absorption band maximal at 590 mμ	Vivid blue color with antimony trichloride, absorption band maximum between 615 and 620 mμ

The manner in which vitamin A exerts its action is not known precisely, but it probably acts in chemical combination with other substances as an oxidation-reduction catalyst.

A second vitamin A, called vitamin A₂, is present in some fish-liver oils, but, except in those from fresh-water fish its concentration is very much lower than the vitamin derived from β -carotene. This latter form is now often referred to as vitamin A₁. Vitamin A₂ is believed to differ chemically from A₁ in possessing an additional CH₃ group and an extra conjugate double bond. In antimony trichloride it shows an absorption band maximal at 696 m μ . It is the predominant form found in the livers of fresh-water fish (see p. 970) but has not been obtained from the livers of mammals.

The relation of vitamin A₁ to rhodopsin and of A₂ to porphyropsin is outlined in Chapter XXV.

The importance of vitamin A in nutrition and bodily welfare

The following effects result from vitamin A deficiency, which may be due not only to a dietary lack but also to failure in absorption, as in obstructive jaundice and sprue, or to severe liver disease (e.g., cirrhosis) in which the carotene conversion process is impaired.

(a) *Failure to gain in weight.* Since young rats upon diets lacking in vitamin A fail to increase in weight it was thought at first that this vitamin had a specific growth-promoting effect. It has been shown, however, by Orr and Richards from measurements of body length and lengths of limb bones that growth in the true sense is not arrested by vitamin A deficiency. Skeletal growth continues though the animals fail to gain in weight. The weight curve is therefore not a true index of skeletal growth.

(b) *Disorders of the skin.* In man, one of the earliest manifestations of vitamin A deficiency is dryness of the skin followed by a papular eruption due to changes in the hair follicles; the sebaceous glands and sweat glands atrophy. Hyperkeratosis and the formation of keratotic plugs in the hair follicles are seen in man and in rats.

(c) *Xerophthalmia and inflammatory eye conditions.* In xerophthalmia the primary change appears to be in the lachrymal glands whose secretion is suppressed. The corneal surface becomes dry and, having lost the protective and lubricating effect of the tears, becomes invaded by micro-organisms (fig. 249). Inflammation and thickening of the conjunctivae with a purulent discharge, and softening (keratomalacia) leading to ulceration

of the cornea result. Osborne and Mendel observed this condition in 80 per cent of rats placed upon a vitamin A deficient diet. It occurs in the human subject when the diet is lacking in this vitamin and there is no doubt that it is a specific manifestation of such deficiency, since it cannot be produced in animals by the lack of any other vitamin.

(d) *Cornification of epithelial surfaces.* The epithelial linings of the respiratory, alimentary and urinary tracts and the ducts of various glands, tend to become converted to the stratified squamous type with consequent drying up of their secretions. Evans and Bishop observed that the cornified

FIG. 249. Illustrates a baby which had suffered from an attack of ophthalmia of dietary origin, and was cured by administration of fat-soluble A as butter and cod-liver oil. The disease had, however, progressed so far that the sight of the left eye was destroyed and the right eye damaged. (After Bloch, from McCollum and Simmonds, *The Newer Knowledge of Nutrition*.)

vaginal cells characteristic of the estrous period of the rat (p. 747) appeared in animals upon a diet deficient in vitamin A even though the ovaries had previously been removed. The changes in the lachrymal glands, hair follicles and cutaneous glands mentioned above, as well as several other manifestations are special examples of the general tendency toward cornification of epithelial tissues when the diet is deficient in vitamin A.

(e) *Night blindness (hemeralopia or nyctalopia).* This is the failure of vision in dim light which occurs in man and animals as a result of vitamin A deficiency. It is not uncommon in the tropics, and an interesting example of custom anticipating science is the fact that the native treatment for the condition was a poultice of liver to the eyes and the addition of liver to the diet. Night blindness

is also seen in Labrador and certain parts of Newfoundland where the diet in winter is deficient. The condition is due to the failure in regeneration of the visual purple (p. 970) after the eyes have been exposed to bright light. In health, regeneration of the pigment occurs after the eyes have been a few minutes in the dark; whereas in vitamin A deficient animals (rats) the regeneration occurs very slowly or not at all. The relation of vitamin A to the formation of visual purple has been investigated by Wald (p. 970).

It should be emphasized that vitamin A deficiency is not the only cause of night blindness, and even when it is the cause the visual defect cannot always be attributed to failure in the regeneration of visual purple, for degenerative changes in the visual receptors or of the neural elements of the retina may be a relatively early effect.

A method has been devised for detecting mild grades of vitamin A deficiency based upon the measurement of the rate of dark adaptation. The eyes are first accustomed to complete darkness for a period of 10 minutes and then exposed to a bright light seen through the eyepiece of a specially designed photometer (or adaptometer) for 3 minutes. The light is then switched off and the rate of dark adaptation determined for a period of 10 minutes. The clinical value of this test is in some doubt. The determination of the concentration of the vitamin in the plasma is a more sensitive and reliable test. Some believe that impairment of the faculty of dark adaptation, due to mild grades of vitamin A deficiency, may be a contributory factor in many motor accidents occurring at night.

(f) *Degenerative changes in the nervous system.* Mellanby reported that there occurred in dogs upon a diet rich in cereals and deficient in vitamin A a condition resembling subacute combined degeneration of the cord in man (p. 868). Wolbach and Bessey conclude, however, from their experiments upon growing rats that the effect of vitamin A deficiency upon the nervous system is not direct, but is of mechanical origin due to the retardation of the growth of the bones of the vertebral column.

There is some evidence that vitamin A deficiency in man in certain instances leads to optic neuritis. Degenerative changes in the layers of the retina including the outer portions of the rods have been described as resulting from vitamin A deficiency and it is probable that the changes in the rods are responsible, in many instances, for night blindness in vitamin A deficiency. Degeneration of other cranial nerves, especially of sensory fibers, were also observed in Mellanby's animals and is

due most probably to pressure by bony overgrowth.

(g) *Susceptibility to infections.* In animals, abscesses at the base of the tongue; genito-urinary and respiratory infections; abscesses of the middle ear and nasal sinuses, as well as the inflammatory eye conditions already mentioned, are very frequent results of vitamin A deficiency. Also, mice upon A-deficient diets succumb more readily than do normal mice to the administration of paratyphoid cultures (Lassin).

In considering the possibility that the foregoing results of vitamin A deficiency in animals have a bearing upon similar infective conditions in man the question must be considered from two points of view: (a) Is the vitamin A content of the diet in a proportion of the general population actually reduced to a level at which such infective conditions are likely to arise? (b) Does vitamin A in excess of the quantity present in a diet, judged by

Cervical Segment I

FIG. 250. Shows degeneration in spinal cord of dog fed on a vitamin A-deficient diet. (After E. Mellanby *Nutrition and Disease*.)

the usual criteria to be quite adequate, raise the resistance of the individual, and so serve a preventive or curative function in infective processes? With regard to the first question:—the diets of the population of this continent, according to Hess and his colleagues, is rarely deficient in vitamin A, that is, lacking to the degree at which the generally recognized signs of vitamin A deficiency appear. Nevertheless, it is still possible that a vitamin A intake somewhat above this level is required to maintain a high resistance against ordinary infective processes, and that in this sense a mild degree of vitamin A deficiency is not uncommon. This is a difficult question to decide, but there is little evidence that such is the case. The vitamin A stores of persons dying of infective diseases are not lower than the stores of those dying from other causes. When the vitamin A deficiency, however, reaches the point where skin disorders or xerophthalmia develop it is to be expected that, as in

animals, the susceptibility to various infective conditions will be increased. One can readily believe that the changes in the epithelial surfaces (cornification) mentioned above would be conducive to infective processes, since healthy mucous membranes constitute a "first line of defence" against the invasion of microorganisms.

With regard to the second question:—does vitamin A in excess, i.e., above the quantity contained in the average diet, exert a specific prophylactic or curative action in respect to infective processes generally? The evidence is conflicting. Mellanby and Greene believe as a result of their investigations that vitamin A concentrates increase the resistance to puerperal sepsis and septicemia. They have spoken of vitamin A as the anti-infective vitamin. They reported that in cases treated with the vitamin before confinement the incidence of septic conditions was very much lower than in those not treated. They also stated that the mortality rate of a group of septicemic cases treated with the vitamin (and receiving a diet of high nutritional value as well) was less than a third of that of cases treated in the usual way. Ellison found that in a series of pneumonia cases secondary to measles the mortality in those receiving vitamin A was less than half that in the same number of control cases, and Donaldson and Tasker reported that the mortality rate of adult pneumonia patients treated with vitamin A was 44 per cent lower than that of patients to whom the vitamin had not been administered. Other observers, however, have been unable to demonstrate any beneficial effects of the vitamin upon the incidence or course of various infections, respiratory, pharyngeal, aural, etc., or of the common cold provided that no actual vitamin A deficiency existed. Hess could observe no beneficial effect—gain in weight or increased immunity—in infants as a result of adding vitamin A to the diet. Also in an investigation carried out by Mackay upon infants the incidence of general infections was not reduced in the group receiving vitamin A. Nor did Ellison find that the administration of the vitamin reduced the incidence of ear disease following measles. Since no unequivocal evidence of vitamin A having a specific anti-infective function has been brought forward, the question must remain undecided for the present. It seems wiser, quoting Mendel, "To stress the indefinite function of the vitamin in preserving 'health and vigor' rather than to herald any specific action against definite microbiotic enemies." This probably applies equally well to other vitamins.

(h) An antagonism between vitamin A and the thyroid hormone has been demonstrated. The loss in weight of rats caused by daily injections of thyroxine can be prevented by the administration of carotene. It has also been shown that the stores of vitamin A in the livers of guinea-pigs are reduced by injections of thyroxine and the metamorphosis of tadpoles treated with thyroxine can be delayed by treatment with vitamin A. It appears that the thyroxine effect is due to its causing rapid destruction of the vitamin and not because it prevents the conversion of the provitamin. Indeed in *hypothyroidism* the conversion of carotene to the vitamin is defective; the milk of goats, which ordinarily is pure white, becomes yellow after thyroidectomy, due to the excretion of unchanged carotene.

(i) *Renal function.* Pathological changes in the kidneys have been reported by several workers as resulting from vitamin A deficiency in animals as well as in man. Vacuolization and calcification of the cells of the convoluted tubules, cloudy swelling of the cells of the collecting tubules and hyperplasia and cornification of the epithelium of the renal pelvis have been described. The experiments of Herrin and Nicholls indicate that vitamin A plays an important rôle in renal physiology. They demonstrated a reduction up to 40 per cent in the urea clearances of dogs upon vitamin A deficient diets. The clearances were restored to normal by the administration of adequate amounts of the vitamin. On the other hand, the urea clearances were raised by from 42 to 100 per cent above the normal in dogs receiving large doses of vitamin A.

(j) The relationship of vitamin A to urinary lithiasis is discussed on p. 721.

THE VITAMIN B COMPLEX

The first vitamin to be discovered was called the antineuritic vitamin since its absence from the diet was shown to be the cause of beri-beri (see below). When the practice was adopted of referring to the vitamins by letter it was designated vitamin B. Later work showed it to be a combination of several vitamins, one is antineuritic and now known as vitamin B₁ or *thiamin*; the other components of the B complex are, *riboflavin*, *nicotinic acid* or *niacin*, *pyridoxin*, *pantothenic acid*, *inositol*, *biotin*, *para-aminobenzoic acid* and *choline*.

The grouping together of these water soluble vitamins under the heading, B complex, is not artificial and simply a convenience, but based upon a common wide distribution and close association in vegetable and animal tissues, and upon their intimate functional interrelationships. They are of importance for the growth or metabolism of various forms of life from bacteria, protozoa and yeasts to mammals. They presumably form an essential part of the enzyme systems underlying

living processes. Several have been shown to be synthesized, to some degree at least, by bacteria in the intestinal tract of higher animals.

THIAMIN⁴ OR VITAMIN B₁ (ANTINEURITIC)

Chemical properties of B₁. This factor is soluble in water and in 70 per cent alcohol or acetone. In acid media it is resistant to heat, remaining active for several hours after heating, with free access of air, to 100°C. It is, however, less resistant to heat than B₂, being destroyed at high temperatures (autoclaving), and is therefore spoken of as the *heat-labile* factor of the B complex, the B₂ factor being referred to as the *heat-stable* factor. B₁ is resistant to strong acids but is readily destroyed by alkali. It is adsorbed from solution by Fuller's earth. It was isolated as the chloride in crystalline form by Jansen and Donath in 1926. 0.002 mg. of this preparation was stated to cure polyneuritis in pigeons. It was given the following tentative formula by Windaus and his associates—C₁₂H₁₈N₄OSCl₂. This is the only vitamin containing sulphur and for this reason has been named *thiamin*. Thiamin was synthesized by Williams in 1936. The following is the structural formula of thiamin chloride hydrochloride.

Thiamin chloride hydrochloride

Distribution and requirement. The chief sources of vitamin B₁ are, liver, kidney, lean meat, especially pork, the germ of wheat, rye or corn rice polishings, soy bean, peanuts, and green or dried peas and beans. Smaller amounts are present in egg-yolk, fresh milk, potatoes, turnips, bananas and various nut kernels. The several factors of the B complex tend to show roughly parallel distributions; foods, for example which have a high content of thiamin are generally rich in other B factors.

The daily adult human requirement is around 0.6 mg. per 1000 calories.

Effects caused by vitamin B₁ deficiency

(a) *Beri-beri—polyneuritis.* Beri-beri is a disease which for centuries has been prevalent in rice-

⁴ Also spelled *thiamine*.

eating countries, e.g., Japan, China, India, Dutch Indies, Philippine Islands, etc. It is also occasionally seen in Labrador and Newfoundland and in young children upon deficient diets. The disease is characterized by inflammation of the peripheral nerves (polyneuritis) which leads to progressive paralysis of the limbs and sensory disturbances. There is also dilatation of the right heart. The disease occurs in two forms one with edema (wet type) the other without (dry type). The first definite indication that beri-beri was of dietary origin was obtained (1885) by Takaki, a medical officer of the Japanese Navy who by revising the

FIG. 251. Upper photograph, dog, showing polyneuritis with marked paralysis of hind limbs as a result of a diet lacking in vitamin B. Lower photograph, the same animal cured by vitamin B, given in the form of tomato juice. (After Cowgill and Mendel.)

diet of the sailors practically eradicated the disease from the service. He thought however that the disease was due to protein deficiency and replaced a part of the polished rice of the diet by meat, milk, wheat and barley. The experimental investigation of beri-beri dates from 1890 when the Dutch physician Eijkman observed a disease in fowl at his laboratory in the Dutch West Indies which he believed was of the same nature as the human condition. The affected fowl had received a diet of polished rice, i.e., rice from which the pericarp (bran) and germ had been removed by milling (see fig. 259, p. 661). It was soon shown by

others (Fraser and Stanton) that the condition in fowl and beri-beri in man could be cured by the addition of rice polishings to the diet or an extract prepared from them. The subsequent preparation by Funk of a crystalline substance of high antineuritic potency from rice polishings has been mentioned (p. 635).

Polyneuritis is readily induced in pigeons by a diet composed exclusively of polished rice. Retraction of the head and paralysis of the limbs are outstanding features. B₁ deficient diets cause analogous symptoms in dogs and rats (see fig. 251). The oxygen consumption of the brain tissue is reduced. An accumulation of lactic acid in the hind-brain (Kinnersley and Peters), liver, heart and muscles of birds occurs in the advanced stages of the disease and the lactic acid of the blood is raised. The head retraction is probably due to the increased concentration of lactic acid in the brain substance; the symptom is quickly abolished by the local injection of the vitamin. A high carbohydrate diet intensifies the effects of B₁ deficiency which fact taken together with the high lactic acid concentration just mentioned, suggests that a fault in carbohydrate metabolism (possibly with the formation of toxic substances) exists. Hyperglycemia and depletion of liver glycogen occur in polyneuritic pigeons. Though this may be due in part to inanition, for Drummond and Marrian observed it in starved pigeons receiving adequate amounts of vitamin B₁, it is mainly a direct effect of the avitaminosis. The abnormally high glucose tolerance curves (i.e., reduced glucose tolerance) of rats showing signs of B₁ deficiency also furnish evidence of a disturbance of carbohydrate metabolism (Lepkovsky and associates). *In vitro* experiments indicate that an action of B₁ is to aid in the oxidation of carbohydrate in the brain through the lactic acid stage. For example, sliced brain tissue from an animal (pigeon or rat) suffering from vitamin B₁ deficiency does not consume the normal amount of oxygen when lactic acid is added to it; pyruvic acid also appears in the avitaminosis brain tissue but not in the normal brain. The addition of vitamin B₁ partially corrects these defects; the oxygen usage is increased and the production of pyruvic acid is reduced. The vitamin exerts a negligible effect upon the respiration of healthy brain tissue. The removal of pyruvic acid is normally, according to Peters, an oxidative process, dependent upon an enzyme, pyruvate oxidase, which cannot function in the absence of thiamin. Thiamin (either free or as the pyrophosphate) is thus considered to be a

coenzyme⁵ for pyruvate oxidase, acting in the enzyme system of the tissues as a hydrogen transporter. The accumulation of pyruvic acid inhibits in turn the removal of lactic acid. Failure in the disposal of both these intermediaries of carbohydrate metabolism therefore occurs in the avitaminosis brain.

The vitamin B₁ requirement is influenced by several factors, e.g., the nature of the diet, the quantity of food consumed and the basal metabolism. It is increased by a diet high in carbohydrate but reduced by one high in fat. The onset of polyneuritis in pigeons on a low B₁ intake, for example, is hastened if the caloric intake is made up largely of carbohydrate and delayed by replacing a part of the carbohydrate by fat. Evans and Lepkovsky showed that the thiamin requirement for the growth of rats was considerably lowered by a high fat diet. This effect of dietary fat is spoken of as its "sparing effect" upon the B₁ requirement. It does not appear, however, to be a true sparing action, for no significant difference is demonstrable between the thiamin content of the tissues of B₁ deficient animals on high and low fat diets, respectively. The experiments of McHenry and his associates indicate a relationship between the actions of choline, thiamin and fat metabolism. They found that in young rats on a choline-free diet an increase in the body fat and liver fat follows the oral administration of B₁. If vitamin B₁ is lacking from the diet, a low choline intake is followed by an increase of liver fat for a short time only—presumably, only until the body stores of B₁ are exhausted. These observers, as well as Whipple and Church, suggest that vitamin B₁ influences the conversion of carbohydrate (possibly via pyruvate) to fat.

(b) *Arrested growth* (fig. 252). Osborne and Mendel found that "protein-free" milk supplied a substance necessary for the growth and well-being of rats. They concluded that this substance was identical with the antineuritic vitamin. It is now recognized that B₁ as well as other factors of the B complex influence growth. Loss of appetite, which leads to undernutrition, is, however, a contributory factor in the retardation of growth resulting from a deficiency of this vitamin. In infants the failure to gain at the normal rate though the diet appears to be adequate, is considered in some instances to be due to a low B₁.

⁵ Thiamin does not serve merely as an activator of the enzyme, as the term coenzyme might lead one to suppose, but is regarded as an integral part of the enzyme molecule.

intake. Tisdall has reported that in a group of young children to whom a concentrate of the B complex was administered, the rate of weight gain over a period of seven months was 1.6 times that of a control group on the same diet but receiving no additional supply of the vitamin.

(c) *Loss of appetite and atony of the gastro-intestinal tract.* Loss of appetite is an early effect of vitamin B₁ deficiency, being evident some time before the appearance of polyneuritis. It occurs in rats and dogs and in human beri-beri. It is probable that the anorexia is, in part at least, secondary to a relaxed state of the gastro-intestinal

plex, notably, pantothenic acid, have a greater influence.

(d) *Bradycardia (in rats and pigeons).* Marked cardiac slowing was observed by Carter and Drury in pigeons fed upon polished rice; it was shown to be due to increased tone of the vagus center; it is abolished by vagal section or atropinization. Drury, Harris and Maudsley observed an extreme degree of bradycardia in rats upon diets deficient in vitamin B₁ but in these animals it is not of vagal origin; it arises in the sinus node. The administration of material rich in vitamin B₁ restores the cardiac rate to normal within an hour or so. It has been shown by Birch and Harris that lactic acid accumulation in the cardiac tissue is associated with the phenomenon.

(e) *Alcoholic psychoses* are believed in many instances to be due, in part at least, to a deficiency of the antineuritic vitamin. The addict receives a large proportion of his caloric requirement in the form of alcohol which is vitamin free. Vitamin B₁ deficiency, rather than a direct toxic effect of alcohol, is held responsible for the aggravation of preexisting cardiac disease and the precipitation of cardiac failure (if not for originating it) which is of such frequent occurrence in chronic alcoholism. In other words, the drunkard may show in varying degrees the cardiac features of beri-beri. The low storage capacity of the body for thiamin as compared with that of the other vitamins apparently accounts for the fact that signs of deficiency of the former are the first to make their appearance.

FIG. 252. Average gain curves of rats on vitamin B-free diet plus daily supplement of ground whole wheat of 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8 and 0.10 grams. Negative controls (marked 0.0) received basal diet only. *P, point where, on the average, chronic symptoms of polyneuritis appeared. Lines broken from the points at which some individuals died. (After Chase, from Sherman and Smith, *The Vitamins*.)

musculature and the reduction in motor activity of the gastro-intestinal tract which have been shown by Cowgill and associates to be important features of vitamin B₁ deficiency. McCarrison produced atony of the bowel and degeneration of the mucous membrane of the colon in monkeys by feeding diets lacking in the B₁ vitamin but of high carbohydrate content. It is not unlikely that in many diets which are assumed to be adequate, the B₁ content is below the optimal level, and that gastro-intestinal abnormalities are not uncommonly the result of mild grades of deficiency of this vitamin, or other factors of the B complex. Recent work indicates that the effect of thiamin upon gastro-intestinal function has been exaggerated and that other components of the B com-

*Riboflavin*⁶ belongs to a group of yellow fluorescent pigments called *flavins*. This factor is responsible for a part of the growth promoting property of the B complex. The flavins are soluble in aqueous media and for this reason are called aqueous media and for this reason are called lyochromes as distinguished from the fat soluble pigments—the lipochromes. Flavins are widely distributed in animal tissues—liver, kidney, milk, etc. Riboflavin, has been synthesized, and has the following formula:

Riboflavin

⁶ Confusion in terminology sometimes arises owing to the fact that riboflavin is referred to by some as vitamin B₂ or as vitamin G.

The daily adult human requirement of riboflavin is between 2 and 3 milligrams.

Riboflavin undergoes phosphorylation forming the mononucleotide riboflavin phosphate which is bound as a prosthetic group to protein. The resulting *flavoprotein* can act as an acceptor and as a donator of hydrogen ions (see p. 330).

In man riboflavin deficiency has been recognized as the cause of certain well defined ocular lesions. In the milder grades of deficiency, examination with the slit lamp (p. 992) reveals congestion of the vessels of the limbic plexus at the periphery of the cornea and the invasion of the subepithelial layer of the cornea by loops of capillary vessels. When the deficiency is more severe the vascularization of the cornea is obvious to ordinary inspection; the eyes appear bloodshot. Burning, itching and lachrymation are complained of. There is photophobia which may be so severe as to prevent the eyes from being opened. Interstitial keratitis may be a later development. Another effect of riboflavin deficiency is the development of fissures and sores at the mucocutaneous margin at the angles of the mouth (*cheilosis*).

Nicotinic acid (niacin) and nicotinic acid amide (pellagra preventive factor)

Chemistry, metabolism and function. The formula of nicotinic acid and nicotinic acid amide are shown below:—

Nicotinic acid

Nicotinic acid amide

Nicotinic acid, though related to nicotine (from which it can be derived through oxidation by nitric acid or potassium permanganate), does not exhibit the action of nicotine upon the autonomic nervous system and is relatively non-toxic. It

does, however, cause peripheral vasodilatation with flushing of the skin when injected intravenously. Nicotine absorbed in smoking cannot be converted into the vitamin. Trigonelline and nicotronic acid are end products of nicotinic acid metabolism; after the administration of the vitamin to man, the dog or the rat, these substances appear in the urine.

Synthesis of nicotinic acid has been shown to occur in rats, sheep and chicks and is brought about largely by bacterial action in the intestine, though in the chick, at any rate, synthesis also appears to be a function of the body tissues.

This vitamin acts principally as a hydrogen transporter in tissue respiration. Co-enzyme I (diphosphopyridine nucleotide) (p. 330) and co-enzyme II (triphosphopyridine nucleotide) are derivatives of nicotinic acid amide. A reduction of the former enzyme has been demonstrated in the tissues of animals suffering from nicotinic acid deficiency. The concentration of these enzymes in the blood of normal human subjects, as well as of those suffering from pellagra is raised by the administration of nicotinic acid. The function of this vitamin is closely associated with the metabolism of carbohydrates, the requirement being raised in diabetes when the consumption of carbohydrate or the insulin dosage is increased.

Sources and requirement. Liver (especially pork liver) kidney, brewer's yeast, whole rye, wheat germ, soy bean and peanuts, are among the richest sources of nicotinic acid. Other good sources are, bananas, almonds, beans, and wheat bran. The daily adult human requirement lies between 20 and 30 mg.

Effects of nicotinic acid deficiency

Deficiency of nicotinic acid or its amide is the cause of the main symptoms of *pellagra* and of the condition in dogs known as "*black tongue*."

Pellagra. The chief features of pellagra (= rough skin) are patches of dermatitis, redness and soreness of the tongue together with digestive disturbances and diarrhea. Nervous disorders (muscular weakness, tremor paresthesias) may occur, and in the later stages melancholia, dementia or delirium. The skin lesions consist of redness, dryness and the formation of scales upon surfaces exposed to the sun's rays, e.g., the backs of the hands (or the insteps of persons who go barefoot), the neck, cheeks and bridge of the nose. A reddish pigment is excreted in the urine. Degeneration of the spinal tracts, especially of the posterior columns, and of nerve cells in brain and cord is not uncommonly seen post mortem.

Just as beri-beri is a disease affecting those who subsist mainly upon a diet of polished rice, so pellagra is a maize-eater's disease. The condition results whether the maize is whole or has had the pericarp and germ removed. It is prevalent among the poor of the Southern United States, of Spain, Italy and other European countries. It is rare in England, Canada and the Northern United States. The dietary origin of pellagra was clearly demonstrated by Goldberger. He carried out an experiment upon twelve prisoners who in return for a promise of pardon volunteered to submit to a diet of cornmeal, cornstarch, rice, syrup, sweet potatoes and pork fat. At the end of six months pellagra was diagnosed in half the subjects. The other prisoners who received the ordinary institutional fare showed no signs of the disease. At first, Goldberger thought that the disease was due to protein (amino-acid) deficiency but as a result of subsequent experiments upon animals came to the conclusion that a vitamin deficiency was the principle causative factor, and it soon became evident that autoclaved yeast, wheat germ and other substances rich in vitamin B would prevent or cure pellagra.

Most subjects of pellagra also suffer from deficiencies of other factors of the B complex, the administration of nicotinic acid alone being as a rule insufficient to effect a complete cure.

"Black tongue" in dogs is a condition analogous to human pellagra. Necrotic areas appear upon the tongue and the buccal mucosa, and a pellagra-like dermatitis of the scrotum develops in animals receiving a diet free from vitamin B₆. A pellagra-like condition also develops in rats upon diets lacking in this vitamin.

Until the last few years the factor in the B complex which prevents pellagra (P.P. factor) had eluded discovery. Funk as early as 1911 reported the presence of *nicotinic acid* in his extracts but its physiological significance was not realized. Warburg recognized its presence in association with tissue respiratory enzymes and was aware of its fundamental importance in the oxidative processes of the cell. In 1937 Elvehjem and his colleagues isolated nicotinic acid and its amide from liver and discovered that it cured "black tongue" in dogs. Shortly afterwards it was used with outstanding success by Spies and his associates in the treatment of pellagra.

Certain mental and neurological manifestations, e.g., clouding of consciousness, rigidities and unusual grasping and sucking reflexes have been

attributed to nicotinic acid deficiency. Improvement has followed administration of the vitamin.

Pyridoxin or Vitamin B₆ (antidermatitis factor) Rats upon a diet lacking in vitamin B₆ develop skin disorder (rat dermatitis or acrodynia) characterized by redness, scaliness and loss of hair. It is now agreed that the antidermatitis effect is due to the B complex which has been recognized for years. Vitamin B₆ was synthesized by Harris and Folkers in 1939. It has the following formula:

Pyridoxin (2-methyl-3-hydroxy-4,5-dihydroxy-methyl) pyridine

Spies and Ashe have reported that certain symptoms in pellagrins and subjects of beri-beri, namely extreme nervousness, insomnia, irritability, abdominal pain and difficulty in walking, which are not relieved by nicotinic acid, thiamin, or riboflavin, are abolished in dramatic fashion by pure B₆ (synthetic).

There are also indications that this vitamin is of importance in hemoglobin synthesis and in the manufacture of red cells. Dogs and pigs on a diet deficient in pyridoxin develop a hypochromic microcytic anemia which is quickly cured when the deficiency is corrected. Also, in rabbits rendered anemic by repeated bleedings, hemoglobin regeneration and erythrocyte production are hastened by the administration of pyridoxin. The vitamin is also necessary for the normal growth of rats; an assay method is based upon this fact.

The essential importance of B₆ in the life of many lower forms has been demonstrated. It is necessary for the growth of yeast, of mosquito larvae and of several types of microorganisms (Streptococcus hemolyticus, Staphylococcus albus and lactic acid bacillus).

The richest sources of pyridoxin are certain vegetable fats, wheat germ, yeast, legumes, and meat products, especially muscle and kidney. Benefit from its use has been reported in Parkinsonism, muscular dystrophy and myasthenia.

gravis, but hopes that it would be of real value in these nervous disorders have been on the whole disappointed.

Pantothenic acid (chick antidermatitis factor). This component of the B complex has the following formula:—

Pantothenic acid (α - γ -dehydroxy- β , β -dimethylbutyryl-aminopropionic acid)

It was found by Williams and his associates in extracts of various plant and animal tissues and was shown to stimulate the growth of yeast. Like the other factors of the B complex already considered, pantothenic acid has been synthesized. Its identity with the factor which for some time has been recognized as preventing dermatitis in chicks is now established. Lesions of the spinal cord and eye symptoms are also produced in chicks by a deficiency of this factor. It is necessary in the diet of the hen for the hatchability of the eggs, and for egg-laying in pullets. This vitamin has a very wide distribution but the richest dietary sources of this vitamin are liver, kidney, egg-yolk, wheat bran, brewer's yeast, broccoli, molasses and peanuts.

The rôle played by pantothenic acid in human nutrition has not been elucidated, though its function appears to be bound up with that of riboflavin. Its concentration in the blood of subjects of pellagra, beri-beri and of riboflavin deficiency is from 23 to 50 per cent (Spies) below normal, and a rise in the riboflavin content is accompanied by a corresponding rise in pantothenic acid.

Renal, adrenal and cardiac damage and dehydration of the tissues are found in rats with pantothenic acid deficiency. There is also an increased appetite for salt, which is probably the result of the adrenal defect. This vitamin has been termed an anti-gray hair factor since it prevents graying of the fur in black rats. Depigmentation of the feathers of fowl suffering from a deficiency of pantothenic acid has also been reported. These results upon animals cannot be transferred to man. No definite evidence of a factor which prevents the graying of human hair has yet been secured.

About 3 milligrams of this vitamin are excreted daily in the urine of man.

Inositol. (mouse anti-alopecia factor). $\text{C}_6\text{H}_8(\text{OH})_6$, a carbohydrate is found combined with phosphate in cereals and in the phospholipid

of soy bean. It is also present in liver and muscle. This factor is necessary for the normal nutrition of the mouse. When lacking from the diet of young mice, growth is arrested and hair fails to grow over the trunk. Its function in other species and in human nutrition is unknown, but the possibility of its being of benefit in certain skin lesions, e.g., psoriasis, has been suggested. Inositol is synthesized by bacteria in the intestinal tract, but the presence of pantothenic acid is necessary for synthesis.

Biotin. This factor of the B complex is necessary for the growth of yeast and as a growth stimulant or requirement of certain bacteria and fungi. Its chemical constitution was determined by du Vigneaud and his associates and its synthesis effected by Harris and his colleagues. The structural formula of biotin (2'-keto-3,4,imidazolido-tetrahydrothiophenovaleric acid is shown below:—

Biotin

Rats fed upon egg-white develop a severe dermatitis (egg-white injury) which has been shown to be due to the presence of a protein known as *avidin*. Avidin combines with biotin and by rendering the latter unavailable induces biotin deficiency. Thus, biotin occurs in a bound form (*avidin-biotin*) which is inactive and as a free active form. Biotin is not liberated from its combination with avidin by the digestive, proteolytic enzymes, but separation can be brought about by oxidative procedures, e.g., treatment with hydrogen peroxide. Avidin appears to be associated in some way with the female reproductive functions; stilbestrol administration followed by progesterone causes the production of this protein in the oviducts of immature chicks.

Biotin is found in relatively large amounts in liver and kidney. It is present in lower concentrations in egg-yolk, tomatoes and carrots. Certain types of carcinoma contain it in relatively large amounts. This finding has suggested

the possibility that, by reducing the free biotin content of the diet, inhibition of cancerous growth might be brought about.

Para-aminobenzoic acid. This factor has the following formula:—

Para-aminobenzoic acid

It is essential for the growth of certain micro-organisms and antagonizes the bacteriostatic action of the sulfonamides. The resistance to these bacteriostatic agents which is shown by *Staphylococcus aureus* is due to the ability of this organism to synthesize para-aminobenzoic acid. This factor is also an essential constituent of the diet for the normal growth of chicks and in combination with inositol, prevents decoloration of the hair (achromotrichia) of rats. The effect upon the growth of chicks is probably an indirect one, namely, the stimulation of the growth of intestinal bacteria and the synthesis of known growth-promoting factors

Choline .(See p. 601.)

VITAMIN C (ANTISCORBUTIC)

Properties

Vitamin C has been shown to be a relatively simple chemical substance closely allied to hexuronic acid. It has been appropriately named *ascorbic acid* ($C_6H_8O_6$).⁷

Ascorbic acid was isolated by Szent-Györgyi in 1928 from oranges, lemons and cabbages and from the suprarenal cortex. It was shown to have a high antiscorbutic potency. Almost simultaneously King and Waugh obtained crystals of ascorbic acid from concentrates of lemon juice which were capable in 0.05 mg. daily doses of protecting a guinea pig from scurvy. It was later synthesized by Hirst and associates who gave it the following structural formula.

⁷ This is also referred to as *cevitamic acid*, a term recently adopted by the American Council on Pharmacy and Chemistry.

L-Ascorbic acid—Vitamin C

Ascorbic acid has a high reducing power, soluble in water and alcohol, and is readily destroyed by heat, sunlight and oxidizing agent. Prolonged boiling, drying, aging or storage of food reduces or abolishes their antiscorbutic properties. Copper catalyzes the oxidative process, so that the vitamin is destroyed much more readily when foods are cooked in a copper utensil than when glass, enamel or aluminum vessels are employed. Nevertheless, boiling milk even in an enamel vessel for five minutes destroys 20 per cent of its vitamin C content. Heating to 60°C. for thirty minutes (pasteurization) in a copper vessel destroys 80 to 90 per cent of its vitamin C value but only a negligible loss occurs if the pasteurization is carried out in an aluminum or enamel container. In general, slow cooking, e.g., stewing is more destructive to the vitamin than more rapid cooking even at a higher temperature. There is said to be little loss of vitamin C in the commercial canning of fruit.

The essential function of vitamin C appears to be the maintenance in a normal state of the intercellular ground substance in which the tissue cells are embedded and cemented together. The matrix of bone and of dentine, the cement substance between the cells of the capillary walls and the ground substance of the general connective tissues, etc. are produced by the supporting or collagenous cells (e.g., fibroblasts, osteoblasts, etc.). As originally formed the material, according to Wolbach is liquid but after its production becomes, under normal circumstances, transformed into a semi fluid gelatinous mass in which the tissue cells are embedded. It is the view of Wolbach that the gelation process and the maintenance of the gelatinous state are dependent upon the action of vitamin C. The manner in which the antiscorbutic vitamin exerts its effect is unknown. There is ample evidence that it serves as a hydrogen trans

porter in the respiratory enzyme system of plant cells, but evidence of its playing a corresponding rôle in animal tissues is inconclusive. The respiratory activity of scorbutic tissues is not reduced nor does an increase in oxygen consumption result from the addition to such tissues of ascorbic acid.

The distribution of vitamin C

The richest sources of this vitamin are the citrus fruits (oranges, lemons, grapefruit and limes), cabbage, swedes and turnips, tomatoes, spinach, green and red peppers. Fresh meat, cow's milk and other animal foods are very poor sources of vitamin C. Its concentration is several times greater in human milk than in cow's milk. The vitamin is stored to a very limited extent in the body. It is in highest concentration in the adrenal cortex. Of other tissues, the crystalline lens, the corpus luteum and the pituitary gland contain the largest amounts. The average concentration in human blood is from 0.7 to 1.0 mg. per 100 cc. From 30 to 50 mg. are excreted daily in the urine.

The synthesis of vitamin C

The precursor from which vitamin C is synthesized in Nature is unknown, but glycuronic and galacturonic acids are likely possibilities. It is synthesized by germinating seeds and in the growing sprouts and tips of plants which contain it in relatively high concentration, whereas it is absent, or nearly so, from dried seeds and the less actively growing plant tissues. Ascorbic acid is formed by the chick embryo and apparently by the adult fowl, the rat, mouse and dog, but not by the guinea pig, the monkey or man. The particular tissue responsible for the process is unknown; it is not dependent, entirely at any rate, upon the adrenals since adrenalectomized rats and dogs survive upon a diet free from vitamin C. This vitamin is now synthesized on a commercial scale from glucose, sorbitol being an intermediate product.

The effects of vitamin C deficiency

Scurvy (scorbutus). The essential pathological change in scurvy is weakening of the endothelial wall of the capillaries;⁸ the intercellular cement substance is reduced in amount. This leads to hemorrhages from various structures, e.g., mucous

membranes of the mouth and gastro-intestinal tract, skin, subcutaneous tissues, muscles and subperiosteal tissues. Redness, swelling, ulceration and, in severe cases, gangrene of the gums result. Some of the main features of the condition are: anemia; small cutaneous hemorrhages (petechiae); pains in the bones and tender swellings, due to subperiosteal or muscular hemorrhages; separation of the epiphyses, especially in young children; great weakness and emaciation. X-ray examination of the scorbutic bone shows a white line running down the outside of the shaft which is not seen in normal bone. In guinea pigs, the clotting time of the blood is prolonged and the platelets and red cells are reduced. There is a progressive reduction in the ascorbic acid content of the adrenal cortex in guinea pigs upon a scorbutic diet; the addition of orange juice to the diet restores the normal content.

In the past, scurvy as an adult disease occurred most frequently upon sea voyages, since fresh food for perhaps months at a time was lacking from the diet. For a similar reason it occurred during military campaigns and exploration parties, or in the general population in times of famine. During world war I it made its appearance among members of expeditions in the East, and among civilians in some of the warring nations. It may also develop in artificially fed infants (*Barlow's disease*). According to Drummond the vitamin C content of the diet of adults is frequently, even at ordinary times, only a little above the level at which scurvy appears. Such grades of vitamin C deficiency may, however, be the cause of anemia, adequate supplies of the vitamin being required apparently for the normal functioning of erythropoietic tissue. Among other pathological conditions in which, in some instances, vitamin C deficiency may play a rôle are, cataract, gastric ulcer and rheumatic fever. However, the evidence adduced to connect hypovitaminosis C with these conditions is inconclusive.

One of the earliest records of the cure of scurvy by the administration of a substance rich in vitamin C is that describing an episode of Jacques Cartier's second voyage to Canada (1535). A number of the explorer's men had died from scurvy and most of those remaining were dangerously ill. These were cured by a drink prepared by a friendly Indian from the leaves and bark of an evergreen tree (probably the spruce).

About the middle of the eighteenth century (1747) Lind, a British naval surgeon, carried out

⁸ The capillary resistance test is described on page 95.

an interesting and entirely admirable clinical research, the results of which showed conclusively the antiscorbutic value of oranges and lemons.

Lind, as he says, "took 12 men in the scurvy on board the 'Salisbury' at sea. Their cases were as similar as I could have them. They all had putrid gums, the spots and the lassitude with weakness of their knees." He grouped them into six pairs. To one pair he gave daily a quart of cider, to another pair elixir vitriol, to the third pair vinegar and to the fourth sea water and an electuary composed of garlic, mustard seed, balsam of Peru and myrrh, together with acidulated barley water as a drink. The fifth pair each had a lemon and two oranges daily. "The consequence was," he records "that the most sudden and visible good were perceived from the use of the oranges and lemons; one of those which had taken them being at the end of six days fit for duty . . . the other was the best recovered of any in his condition . . . and was appointed nurse to the rest of the sick." He also noted some good effect from the cider but none from the other articles. Lind recommended that concentrated lemon juice be rationed to the navy. This advice was not put into effect by the government until 1795, after which the sobriquet "Lime juicer" was given by other nations to the British sailor.

The experimental investigation of scurvy may be taken to date from the work of the Danish scientists Holst and Frohlich (1907 to 1912) who found that the condition developed in guinea pigs kept upon a diet completely lacking in green vegetables, e.g., one constituted solely of cereals. It is possible to induce scurvy only in those species which are incapable of synthesizing the vitamin, namely, in the primates and the guinea-pig.

The vitamin C requirement. Harris and his colleagues have devised a method for determining the vitamin C requirement based upon the urinary excretion of ascorbic acid after a known amount has been given by mouth. Vitamin C is a threshold substance, i.e., it is not excreted in the urine if below a certain level in the blood, which depends in turn upon the requirement or degree of "saturation" of the tissues. If the subject's tissues are "saturated" with vitamin C a large part of the administered dose can be recovered from the urine; if the tissues are "unsaturated" more is retained, the proportion varying with the degree of unsaturation. The vitamin C content of the urine is deter-

mined by titration with 2:6, dichlorophenolindophenol (p. 662). The daily requirement of vitamin C for the adult is from 75 to 100 mg., but it varies considerably. Infections, rheumatic fever and certain other conditions tend to deplete the vitamin stores and therefore increase the amount which must be provided in the diet. Infants require much more relatively to their body weight than do adults. The vitamin stores with which the baby comes into the world are depleted within the first few days and even if breast fed it must receive extra supplies in the form of orange or tomato juice.

Vitamin P (permeability vitamin). Szent-Györgyi and his associates obtained a crystalline substance from lemon juice and Hungarian red peppers which they claimed controlled vascular permeability. This material, which they called "citrin" or vitamin P, was found later to consist of two vegetable dyes (flavonols), *hesperidin* and *eriodictyol glucoside* (demethylated hesperidin). They stated that certain hemorrhagic diseases associated with increased permeability or fragility of the capillary wall were cured by citrin, by lemon juice or by extracts of red pepper but not by ascorbic acid. They found further that the survival time of guinea-pigs upon a scurvy-producing diet was prolonged by vitamin P and that the hemorrhages were less pronounced in those that had received it than in control animals upon the scorbutic diet alone. It was therefore postulated that scurvy was due to a deficiency of both vitamins C and P. After several conflicting reports concerning this vitamin, its existence appears to have been finally established. Its distribution in food stuffs is closely similar to that of vitamin C. Lemon peel is an especially rich source.

The physiologically active principle of vitamin P is believed to be *hesperidin chalcone*. Its formula is:—

Hesperidin chalcone

R is a sugar group.

CHAPTER LVI

THE VITAMINS (*Continued*)

VITAMIN D (ANTIRACHITIC)

Properties. Vitamin D is soluble in fats, oils, ether and alcohol but insoluble in water. It is very stable to heat and to oxidation. It shows an absorption band between 260 and 270 $m\mu$ (maximum at 265). The antirachitic vitamin belongs to the class of substances known as sterols or solid alcohols. Among these are *cholesterol* ($C_{27}H_{46}O$) of animal tissues, *phytosterol* of plants, and *ergosterol* found mainly in fungi (yeast, mushrooms, ergot, etc.). *Ergosterol* was first obtained from mushrooms in 1811. The vitamin has been isolated in crystalline form and named *calciferol*.

The following formula has been suggested for ergosterol by Windaus and Langer:

together the antirachitic effects of these and other articles of diet with those of radiant energy. First it was found that when rats on a vitamin D deficient diet were placed in glass jars which had been irradiated by a mercury vapor lamp they thrived as well as if they had been directly irradiated (Hume and Smith). The beneficial effect, as it turned out later, was due to the animals having eaten the irradiated sawdust in the jars. It was also discovered (Goldblatt and Soames) that the livers of rats which had received no vitamin D in their diet but had been irradiated with ultraviolet light acquired antirachitic properties similar to those of cod-liver oil. The livers of non-

ULTRAVIOLET IRRADIATION AND VITAMIN D

The search for the antirachitic vitamin makes one of the most interesting stories of modern biological science. As early as 1890 Palm suggested that sunlight possessed an antirachitic action, and in 1919 Huldchinsky successfully employed the ultraviolet rays from a mercury vapor lamp for the cure of rickets. Hess and Unger demonstrated in 1921 that sunlight had the same curative effect. By this time Mellanby had published his results proving the antirachitic value of cod-liver oil, egg yolk and butter (see p. 655).¹ It was not long before intensive research by several workers furnished the information necessary to link

irradiated rats were quite ineffective. Shortly after this Steenbock and Black and Hess and Weinstock, independently, showed that certain fat-containing foods which possessed no power to cure rickets acquired this power upon artificial irradiation. It was then discovered by these two groups of observers and at the same time by Rosenheim and Webster that cholesterol of animal tissues (skin, brain, etc.) and sterols of vegetable foods gained antirachitic properties upon irradiation. Cholesterol even after careful purification (re-crystallization some 20 times), and though quite inactive if untreated, became powerfully antirachitic upon irradiation. These sterols apparently were the precursors of vitamin D. Thus the final link in the chain of evidence connecting the antirachitic effect of irradiating the body

¹ Bland-Sutton used cod-liver oil with success in preventing rickets in lion cubs at the London Zoo a number of years earlier.

surface and that resulting from the ingestion of certain foods was forged. Nevertheless, as a result of subsequent research it was concluded by Rosenheim and Webster and by Windaus and Hess (1927) that not cholesterol itself, but minute amounts of ergosterol with which it was contaminated were responsible for the antirachitic effects; ergosterol (of both animal and plant tissues) came to be regarded as *provitamin D* (see p. 651). Ergosterol, obtained from yeast, when irradiated yields a group of substances—*lumisterol*, *tachysterol*,² *calciferol* and *suprasterol*. During irradiation these products appear in the order given, but their proportions in the mixture at any moment depend upon the intensity and duration of the irradiation. Calciferol is not the end result, but at a certain stage the amount of calciferol formed is at a maximum beyond which it undergoes decomposition, and toxisterol is produced. This product of over-irradiation is highly toxic, having a very pro-

The ultraviolet rays effective in activating ergosterol are those which it absorbs, namely those with wave lengths between 250 and 313 $m\mu$. The maximum effect occurs at wave lengths around 280. Rays having wave lengths within this range falling upon the body surface are also effective in the prevention or cure of rickets. The antirachitic action common to irradiated foods and to direct irradiation of the body surface thus received, apparently, an essentially simple explanation, namely, that ergosterol, the provitamin, was transformed in either instance into vitamin D, which when taken in the food was absorbed from the gastro-intestinal tract and when formed in the skin was absorbed into the blood of the cutaneous vessels (see below).

The shortest rays from the sun which reach most localities of the earth have a wave length of about 290 $m\mu$, whereas those from artificial sources such as the carbon arc and mercury vapor lamp

FIG. 253. Scheme of wave lengths of spectrum, showing the range of those possessing antirachitic properties. Figures refer to millimicrons. (Redrawn and modified from Blunt and Cowan.)

nounced effect upon calcium metabolism. Calciferol, which has the greatest antirachitic effect and comparatively little toxic action, is regarded as the pure vitamin and can be isolated in crystalline form from the other products. A daily dose of 0.0001 mg. of irradiated ergosterol is antirachitic for the rat; non-irradiated ergosterol is quite inactive. 0.025 micrograms (0.025 γ) of calciferol daily will prevent the development of rickets in a rat receiving a rickets-producing diet. The photochemical change involved in the activation of ergosterol is simply one of molecular rearrangement, non-irradiated ergosterol being isomeric with calciferol.

² Dihydratachysterol (referred to briefly as A.T. 10) is used therapeutically to raise the blood calcium in tetany. It has a relatively low antirachitic action, and its toxicity is higher than that of vitamin D.

³ Inhibition of such action, as shown by hypoprote thrombinemia, has been induced in rats upon diets deficient in vitamin K, by the oral administration of the bacteriostatic agent, sulfaguanidine (see p. 660).

are around 220³ and 180, respectively (fig. 253). Dust, smoke or water vapor in the atmosphere being opaque to the shorter waves markedly reduce the antirachitic effect of sunshine. Ordinary window glass filters out all rays shorter than 320 $m\mu$. Certain specially prepared types of glass are transparent to a proportion of the effective rays but sunshine transmitted through ordinary glass possesses no antirachitic action.

The antirachitic rays are incapable of penetrating the skin to any considerable extent beyond a depth of about half a millimeter or so. About 80 per cent of the rays with wave lengths between 250 and 300 $m\mu$ are absorbed or reflected from the corneous layer; the remainder are absorbed by the Malpighian layer and the corium. The blood in the capillaries of the corium acts as an effective filter, none of the ultraviolet rays penetrating beyond.

A very interesting observation made by Hou upon birds may be mentioned in this connection. He found that the preen gland (*glandula uropygialis*) serves an antirachitic function. This gland which is situated in the region of the tail feathers secretes an oily substance. During preening the secretion is distributed over the body feathers where it is activated by the rays of the sun. The irradiated material is either absorbed through the skin or obtained from the ingestion of feather particles in subsequent preening operations. Rickets is said to follow extirpation of the gland and is not cured by irradiation of the general body surface. Fur bearing animals probably obtain supplies of vitamin D in a similar manner, though the oily material is secreted not by a single structure but by glands distributed diffusely throughout the skin. The material which exudes becomes spread over the hairs and after irradiation either enters the body again through the skin or is acquired through licking the fur.

The conclusion of earlier workers mentioned on p. 649, namely, that ergosterol was the provitamin in animal skin, has had to be abandoned, for it has been shown that the vitamin D formed by the irradiation of ergosterol is not identical with that produced by irradiation of the skin. Waddell found that cholesterol after irradiation has an antirachitic potency, when tested upon chicks (see below) equal to that of cod-liver oil and therefore much greater than that of irradiated ergosterol. He concludes that the latter though it possesses a high antiarchitic power is not the vitamin D of cod-liver oil or of mammalian skin. In other words, the provitamin which is associated with cholesterol and which undergoes activation in the skin is some substance other than ergosterol. He points out that there is no direct evidence that ergosterol actually exists to any extent in animal tissues. Waddell's findings offer an explanation for certain discrepancies which have been noted in the past between the potencies of irradiated ergosterol and cod-liver oil. It had been recognized

for example, that, per rat unit, cod-liver oil is more effective (about 30 times) than irradiated ergosterol in curing rachitic conditions in chicks. That is, an amount of irradiated ergosterol per gram of body weight which is adequate for the cure of rickets in the rat is inadequate for the chick. An amount of cod-liver oil, on the other hand, which is quite effective for the chick is inadequate for the rat. In the cure of human rickets, irradiated ergosterol in terms of rat units is less effective than is cod-liver oil. These facts had already led many to conclude that cod-liver oil and irradiated ergosterol contained different antirachitic substances. Irradiated cholesterol has also been reported to be more potent than irradiated ergosterol in curing infantile rickets. It has since been shown that 7-dehydrocholesterol present in small amounts in cholesterol is the provitamin of mammalian skin.

Calciferol, or vitamin D₂ as it is now called, an activated 7-dehydrocholesterol or vitamin D₃ (there is no vitamin D₁) are the two antirachitic vitamins of medical interest. The vitamin D produced by the irradiation of the skin or of milk and present in cod-liver oil is 7-dehydrocholesterol; that produced by the irradiation of yeast and which in oily solution has been marketed under various trade names (e.g., viosterol) is irradiated ergosterol (of yeast), i.e., vitamin D₂. Cows fed upon irradiated yeast simply transfer the vitamin to the milk which therefore owes its antirachitic properties to a vitamin different from that in irradiated milk. Several other antirachitic vitamins are known, some of which have been produced by the activation of provitamins prepared in the laboratory, while others are of natural occurrence, e.g., in the liver oils of different species of fish.

The formulae for calciferol and activated 7-dehydrocholesterol are shown below:

Calciferol (vitamin D₂)

Activated 7-dehydrocholesterol (vitamin D₃)

MAIN FOOD SOURCES OF VITAMIN D

Halibut liver oil is one of the richest natural sources of vitamin D. Cod-liver oil and the liver oils of bony fishes generally are other rich sources. Cod-liver oil, however, contains only 100 international units (p. 662) of vitamin D per gram as compared with 1200 units per gram in halibut liver oil. The liver oils of cartilaginous fishes are relatively poor in the antirachitic vitamin. Mammalian liver which is rich in vitamin A is poorly supplied with vitamin D. The cod and other larger fish receive their supplies of this vitamin, in part at least, from the bodies of the smaller fish upon which they feed. These in turn acquire it in a way similar to that in which they obtain vitamin A, i.e., from small plant-eating animal forms (zooplankton, p. 636) which are capable of synthesizing the vitamin. Bills concludes that the cod can also synthesize the vitamin. He does not believe it possible that the large stores of vitamin D in the liver of the cod can be derived solely from the food. That it is produced by the transformation of the provitamin in the fish's skin by radiant energy seems to be out of the question, the cod being a deep-sea fish.

Other animal sources of vitamin D are egg yolk, butter, cream and milk. The antirachitic potency of these dairy products is, as a rule, quite low and depends upon the vitamin D content of the diet and upon the extent to which the animal has been exposed to sunshine. Thus, summer butter is likely to have a higher antirachitic potency than butter produced in winter. Pasteurization does not lower the antirachitic property of milk. The egg yolk of irradiated hens or of hens receiving irradiated ergosterol has a high vitamin D potency. Small quantities of vitamin D are present in beef fat but not in lard.

Vegetable foods are, as a rule, very poor or lacking in this vitamin. It is absent from most vegetable oils (cottonseed, or maize oil) unless

these have been artificially irradiated. Green vegetables and fruits contain insignificant amount. Yeast has a high content of ergosterol and when irradiated acquires a high degree of antirachitic potency. The milk of cows fed upon irradiated yeast or milk after direct irradiation is also powerfully antirachitic.

An ordinary mixed diet is usually poorer in vitamin D than in any other vitamin; for this reason the diet of young children should be reinforced by this vitamin in some concentrated form. Adults probably receive all the vitamin D required in a well balanced diet.

THE EFFECTS OF VITAMIN D DEFICIENCY

Vitamin D is indispensable to the normal calcification of bone. Its absence from the diet is followed by the development of rickets in the young animal or of osteomalacia in the adult.

Infantile rickets (rachitis)

The fundamental feature of this disease is a disturbance of calcium-phosphorus metabolism with consequent defective ossification and the development of various deformities, e.g., *knock knees*, *bow legs*, *enlargement of the epiphyses*, *spinal curvature (scoliosis)*, *malformation of the chest*, *contracted pelvis*, *soft depressible areas in the parietal bones (cranio-tabes)* and the development of *bosses on the temporal bones* (see fig. 254). The natural curvatures of the long bones tend to become exaggerated. The enlargements of the costo-sternal junctions—"beading of the ribs"—causes a series of small swellings on either side of the thorax which is referred to as the "*rachitic rosary*." Dentition is usually delayed. Sweating of the scalp is common.

CHANGES IN BONE STRUCTURE:

The bones are relatively soft and pliable. *Defective calcification of the growing bone and compensatory hypertrophy of the epiphyseal cartilages* are the essential

pathological changes. A section of the epiphyseal junction of a *normal* growing bone shows the following zones in order from the free ends of the bone toward the shaft (fig. 283, p. 713).

- (a) A layer of resting *hyaline cartilage*.
- (b) A layer of *proliferating cartilage* in which the cells are arranged in regular columns paralleling the long axis of the bone.
- (c) A zone of *preparatory calcification*. The cells are still arranged in columns but deposition of calcium phosphate has occurred in the surrounding cartilaginous matrix.
- (d) A zone of *newly-formed bony trabeculae*—the spongiosa—produced through the invasion of the foregoing zone by osteoblasts derived from the periosteum. Marrow tissue fills in the spaces between the trabeculae.

FIG. 254. Child aged 5 years with leg deformity caused by rickets. (After E. Mellanby.)

In a *rachitic bone* the layer of proliferating cartilage is greatly enlarged, being sometimes ten times its normal depth and the cells no longer show their regular columnar arrangement. This layer instead of being sharply demarcated from the zone of preparatory calcification sends finger-like cellular prolongations into the latter which is almost free from mineral deposit. The trabeculae are malformed and have lost their regularity of pattern. They are composed of *osteoid tissue*, i.e., a tissue very poor in or devoid of calcium. The cortex of the bone also may be partially replaced by osteoid tissue the extent to which this occurs varying with the severity of the disease (fig. 255).

On X-ray examination, the osseous abnormalities in a well-developed case of rickets are clearly evident. The entire shadow cast by the bone is less dense than normally and the ends of the bone are not sharply defined but have a "woolly" or

"moth-eaten" appearance (fig. 256). The articular ends also frequently show a concave (cupped) rather than a convex or straight contour. This appearance is due to the lack, or irregular distribution, of mineral in the zone of preparatory calcification. The latter normally presents a clearly defined almost straight band next to the unmineralized layer of proliferating cartilage.

Chemical analysis of the bones reveals a low mineral (Ca and P) content and a relative increase in organic matter and water. The ratio of ash to organic matter in normal, dry, fat-free bone is 3 to 2 whereas in rachitic bone it may be 1 to 2 or

FIG. 255. Upper photograph, normal rib of rat. Rat weight 158 gm. 52 days on complete diet; continuous growth and gain in weight. Lower photograph. Thirty-four days on rickets-producing diet. Marked rachitic lesions. Note increased width and irregularity of proliferative cartilage, absence of calcium deposition, great excess of osteoid in region of metaphysis and about cortex. (After Hess.)

even 1 to 3. The normal Ca:P ratio remains unaltered (see also p. 712).

The inorganic phosphorus of the blood in rickets is lower than normal, i.e., below 3.0 mg. per 100 cc. (it may be as low as 1.0 mg.). This is an early sign. The serum calcium is usually normal unless the condition is complicated by tetany (p. 702). The plasma phosphatase is elevated several fold (Kay) above the normal value. In well-marked rickets the *intestinal contents* tend to become less acid in reaction, the stools which normally are slightly acid, neutral or slightly alkaline become definitely alkaline. Mineral retention is reduced

in the disease, i.e., the calcium and phosphorus balances (p. 711) show smaller positive values than the normal, or are negative.

THE RELATION OF CERTAIN FACTORS TO THE OCCURRENCE OF RICKETS:

(1) *Diet.* Vitamin D deficiency is the prime cause of human rickets, yet a very low intake of calcium or of phosphorus increases the susceptibility to the condition. The disease does not develop upon a minimal mineral intake provided that the vitamin D supply is abundant, nor will a diet high in the bone-forming minerals prevent the onset of rickets or arrest its course if vitamin D deficiency exists. Rickets, for example, may develop in an infant receiving cow's milk as its sole diet or even

FIG. 256. Left hand photograph, rickety bone, tibia of child $1\frac{1}{2}$ years of age. Right, same bone after the child had received daily doses of cod-liver oil for a period of 14 days. (After H. A. Harris.)

when nursed at the breast if the mother's milk is lacking in the antirachitic vitamin. It may be mentioned here that, according to Hess, mother's milk is superior to cow's milk as a protection against rickets which cannot be explained either upon the basis of its mineral content (which is inferior in this regard to cow's milk) or upon its vitamin D potency.

A diet with a high proportion of cereal foods increases the susceptibility to rickets (see p. 656).

(2) *Age and rate of growth.* Rickets is a disease of the first two years of life, though the conditions known as *late rickets* and *osteomalacia*, which are essentially of the same nature, occur in later years (p. 656). The disease may commence a few weeks after birth. The period during which it most frequently makes its

appearance, however, is from the 3rd to the 10th month. It rarely commences after the second year, nor does it usually progress beyond this time, spontaneous healing taking place in the majority of cases around the 12th month. In some occasional instances the disease appears to commence in intra-uterine life—*fetal rickets*. *Premature infants* are highly susceptible to rickets. The possible reason for this is that since the fetus accumulates over 80 per cent of its calcium stores in the last 3 months of intra-uterine life those of the infant born before term are incomplete. Rapidly growing, overweight and apparently robust infants are more susceptible than others. Indeed Glisson (1660) to whom we owe the best classical description of the disease ascribed it primarily to over-nutrition. It was noted by Hess and his associates that rats in which growth was stimulated by a more abundant diet required a greater amount of irradiation to protect them against the disease than others upon the ordinary standard diet. McCollum and associates also found that healing was induced in rachitic rats by a 5-day period of starvation. Cretins, unless stimulated to normal growth by thyroid administration do not, it is said, become rachitic. The growth impulse, therefore, appears to be essential to the development of rickets.

(3) *Climate and season.* In the days before the use of antirachitic measures had become so general, the incidence of rickets was high in the large cities of northern latitudes and for the following reasons.

(a) There are fewer hours of sunshine annually than in southern localities. (b) The sunshine is less intense and the proportion of the shorter ultraviolet rays (300 to 290 m μ) is smaller than in southern climates. The two factors depend upon the sun's altitude—the nearer the sun is to the horizon the greater is the depth of the atmosphere intervening between it and the earth to act as a filter. Rickets is therefore more prevalent during the winter months when the sun reaches its lowest altitude; when this is below 35° the antirachitic effect of sunlight is almost negligible, since few rays shorter than 300 m μ reach the earth. In London and Glasgow which have been noted for their very high incidence of rickets the sun's altitude is less than 35° for 5 and 6 months of the year, respectively, whereas in such cities as Baltimore and Toronto which have shown a relatively low incidence of the disease, the altitude of the sun is less than 35° for only 3 and 4 months, respectively (fig. 257). In Jamaica and other southern localities the sun's altitude is never less than 50° and rickets is almost unknown. Also in temperate climates it is usual for rickets to become arrested during the summer months. A seasonal fluctuation in the blood inorganic phosphorus (low in winter and high in summer) has been found in infants living in temperate zones and appears to be a general phenomenon which again points to the climatic influence upon the susceptibility to rickets. Sunlight exerts its antirachitic effect not only through direct sunshine, but also by reflection from the sky ("sky shine") and from water, light-colored build-

gs, etc. Animals placed out of direct sunlight but exposed to a clear bright sky are protected from rickets. The atmosphere of large cities as a result of its content of smoke, dust and water vapor (humidity) is more opaque to the ultraviolet rays. (d) Children in temperate climates live a greater part of their time indoors during the winter months and expose less of their bodies when out of doors. Ordinary window glass, as will be recalled, is opaque to rays shorter than 320 mμ. Negro children living in temperate climates are

Experimental rickets and the discovery of the antirachitic properties of cod-liver oil

Mellanby produced rickets in puppies by placing them upon a diet of white bread and skim milk, i.e., one deficient in the only fat-soluble vitamin known at the time, namely, vitamin A (fig. 258). The diet included adequate amounts of vitamins B and C. He then showed that animals upon such a diet but receiving in addition cod-liver oil or

FIG. 257. Maximum daily altitude of the sun throughout the year at the latitude of Toronto. (From Tisdall and Brown.)

FIG. 258. A rickety dog. The animal was brought up on a diet deficient in the anti-rachitic vitamin D. (After E. Mellanby.)

especially susceptible to rickets because the skin pigment, which in their natural environment is a protection against excessive ultraviolet irradiation, further reduces the antirachitic effect of solar irradiation in northern latitudes.

There is no reliable evidence that the parathyroid glands or any of the other endocrines are concerned in the production of rickets.

butter (which were then known to be rich sources of vitamin A) developed normally. Linseed or olive oil was not protective. From these experiments the antirachitic property of cod-liver oil was definitely established. Mellanby concluded that vitamin A or a factor associated with it was the antirachitic factor. Experiments by others involving the investigation of the growth-promoting and antixerophthalmic properties of vitamin A aroused the suspicion that a second vitamin was present in cod-liver oil, butter, fat, etc., and that it, and not vitamin A, was the antirachitic factor. It was found for instance that rats on a diet containing 1 per cent of cod-liver oil thrived better than those on one with 20 per cent butter-fat. A much smaller quantity of butter-fat than this contains sufficient vitamin A for the prevention of xerophthalmia. A factor distinct from vitamin A, therefore, appeared to be lacking in butter. It was also observed that children receiving large quantities of milk (rich in vitamin A) sometimes developed rickets. McCollum and his associates furnished the final proof of the existence of two vitamins in cod-liver oil by subjecting this material to oxidation for from 12 to 20 hours. Oil so treated had no antixerophthalmic power (i.e., no vitamin A) but was powerfully antirachitic. He

proposed that this factor which was left undestroyed by oxidation should be called vitamin D. As confirmatory evidence of a separate antirachitic factor it was pointed out that coconut oil though containing no vitamin A furnished a certain protection against rickets. Moreover, it was shown by others that ultraviolet irradiation had no antixerophthalmic action.

Ca:P RATIOS IN THE EXPERIMENTAL PRODUCTION OF RICKETS:

The experimental animal employed most extensively for the study of rickets is the young (20-30 days) white rat. These animals unlike infants (p. 652) and puppies do not, as a rule, when deprived of vitamin D or sunlight develop rickets (though some reduction in bone mineral may occur) provided the diet is otherwise normal. If the vitamin D-free diet is also deficient in calcium or in phosphorus or the relative proportions of these are abnormal, rickets occurs. Unbalanced proportions of the bone forming minerals in the diet are of much greater importance than their absolute amounts. Thus a Ca:P ratio which is too high or too low though the actual amount of P or of Ca respectively is not reduced causes the disease, which can be arrested in turn by the administration of vitamin D or by ultraviolet irradiation. In puppies, and fowl, and apparently in the human subject, an improper balance of these minerals does not seem to be an important factor in the production of rickets. Rickets is also produced in the rat by the addition of magnesium or strontium carbonate to the diet. Beryllium carbonate also, when added in small quantities to a normal stock diet also produces bone lesions in this species similar to those of rickets. This condition is, uninfluenced however, by vitamin D administration.

THE ANTICALCIFYING EFFECT OF CEREALS. It had long been suspected that a high carbohydrate diet was conducive to the development of infantile rickets (p. 652). Mellanby showed the aggravating effect of cereals upon the development of canine rickets. Wheat germ and oatmeal were found to be especially potent in this regard. White flour, rice and other cereals had a less pronounced anticalcifying effect. There appears to be no relationship, however, between the rachitogenic action of these substances and their carbohydrate, protein or mineral contents. The anticalcifying effect is neutralized by vitamin D or by irradiating the cereal itself. The effect was also abolished by boiling the cereal with 1 per cent hydrochloric acid until all the carbohydrate had been converted to sugar. It is believed that Mellanby's results have an important bearing upon the development of human rickets; the influence of cereals upon dental caries is mentioned on page 658.

Mellanby concluded that cereals contained a factor for which the term *toxamine* was suggested. The removal of the toxic effect of the cereal by boiling with HCl was thought to be due to the destruction of this hypothetical substance. The results of the later experiments of Bruce and Callow provide the basis for quite a different explanation. The anticalcifying effect is not due to a toxic substance but to the fact that the phosphorus in such a cereal as oatmeal is in unavailable form, namely, inositolhexaphosphate or phytic acid. Phytic acid combines with calcium and magnesium forming the complex compound phytate. Boiling HCl hydrolyzes this compound, renders the phosphorus, calcium and magnesium available and favors calcification.

Late rickets and osteomalacia

Late or juvenile rickets is essentially the same as infantile rickets but occurs in older children—4 to 16 years. It is a rare condition in western civilization but is seen in India and is then due to the same causes as those which are responsible for the occurrence of osteomalacia. *Osteomalacia* is a failure of ossification of a nature fundamentally the same as that of infantile or late rickets but occurring in adults, especially women. Pathologically it is simply adult rickets. Nevertheless, the fact that it occurs after the period of growth and after puberty, pregnancy and lactation predisposes powerfully to it give it certain features which distinguish it from the infantile or juvenile type. The entire bone is softer than the ordinary ricket bone, its total mineral content being greatly reduced. The calcium shows a greater decrease than does the phosphorus, i.e., the Ca:P ratio is reduced. The magnesium content is increased. The blood calcium is lowered and tetany in consequence is a frequent complication. The calcium balance is negative, whereas the phosphorus balance is usually normal.

The softness and pliability of the bones leads to deformity sometimes of extreme degree. Pelvic abnormalities create serious hazards during childbirth. The disease is very rare in temperate climates though an outbreak occurred in Vienna following the first World War (hunger osteomalacia). Osteomalacia is common in India where the Mohammedan and high caste Hindu women follow the custom of purdah which demands that they live secluded within doors; they are thus deprived of the calcifying power of the sun's rays. The diet too is poor in meat, milk and vitamin D, but rich in cereals. The disease is also common in certain districts of China and is due to similar causes—a cereal diet combined with

in indoor life. Cod-liver oil or some other source of vitamin D is specific for the disease.

Celiac rickets

Celiac rickets is a condition of childhood associated with defective absorption of fat and calcium. As a consequence, fatty diarrhea, a negative calcium balance, low serum calcium, tetany, rarefaction of bone, skeletal deformities, anemia, and dwarfing occur. The condition responds to the administration of vitamin D. A similar condition occurs in adults and is then usually referred to as idiopathic steatorrhea or non-tropical sprue. The absorption of vitamin D is apparently defective in these conditions. The administration of vitamin D or exposure to ultraviolet light is sometimes of benefit.

THE MODE OF ACTION OF VITAMIN D

The precise manner in which vitamin D exerts its effect upon calcium and phosphorus metabolism is obscure. It has been supposed that one of its primary effects was to increase the absorption of these elements from the bowel. Evidence for increased calcium absorption has been afforded by studies of the calcium balance in rickets; irradiation with ultraviolet light or the administration of cod-liver oil converts a negative calcium balance into a positive one. Nevertheless, it would appear that the principal action of the vitamin is more probably the promotion of calcium and phosphorus deposition in the bones. Experiments with dogs given radioactive phosphorus support this conclusion. The toxic effects of the vitamin and its possible relationship to parathyroid function are dealt with in another place (p. 707).

THE RELATION OF VITAMINS A, C AND D TO DENTAL DISEASE

Vitamin A deficiency exhibits an effect upon the epithelium of the gums. In dogs upon A-deficient diets the stratified epithelium of the gingival margins becomes hyperplastic and irregular. In this state the gum readily becomes infected with microorganisms. These findings are clearly pertinent to periodontal disease (pyorrhea) in man. According to Howe, vitamin A deficiency also affects tooth structure, the odontoblasts laying down bone instead of dentine. The former tissue is softer and more porous than the latter. On the other hand, many question that vitamin A deficiency is a factor in the production of human caries. In the study of children, blind as a result of vitamin A deficiency, no evidence was obtained that the latter had an injurious effect upon the teeth.

Vitamin C. In scorbutic guinea-pigs and monkeys

marked changes in tooth structure occur, e.g., (a) disappearance of odontoblasts, (b) decalcification of the dentine which becomes porous, (c) disappearance of canals from the predentine, (d) dilatation of the vessels of the pulp, edema of the pulp tissue and lesions of its nerves. If vitamin C deficiency in man reaches the point where scurvy develops, marked changes in the gingival tissues comparable to those characteristic of the disease in guinea-pigs appear. According to Hanke, vitamin C deficiency in man of a milder degree than that which produces definite scorbutic manifestations may cause changes in the peridontal tissues, pyorrhea and caries. This conception, however, has

TABLE 64*

MODIFICATIONS OF BASAL DIET	AVERAGE NUMBER OF TEETH PER CHILD SHOWING INITIATION OR INCREASE IN CARIES	AVERAGE "DEGREE" OF INCREASE OF CARIES PER CHILD	AVERAGE AMOUNT OF "ARREST- ING" (HARDEN- ING) PER CHILD
1. Abundant fat-soluble vitamins as cod-liver oil added (no oatmeal).....	1.8	2.0	2.0
2. Intermediate amount of fat-soluble vitamins added (no oatmeal).....	3.0	4.0	1.2
3. Comparatively little fat-soluble vitamins (some oatmeal).....	5.8	6.7	0.04
4. Much vitamin D as irradiated ergosterol (basal diet).....	1.0	1.1	3.9
5. Cereal-free diet much vitamin D.....	0.37	0.32	4.7

* Modified M. R. C. Rep. 167.

not been adequately substantiated and the question of vitamin C deficiency in the etiology of ordinary dental caries is a matter for further investigation.

Vitamin D. M. Mellanby some years ago carried out a series of experiments in which the effect of vitamin D and other factors upon tooth structures were thoroughly investigated. Young puppies were fed upon vitamin D deficient diets for periods extending over several months. At the end of the experimental period the animals' teeth were carefully examined with regard to gross appearance and histological structure. The following defects were observed.

- (1) Delay in the eruption of the permanent teeth.

- (2) Thickening of the bony tissue of the jaws and irregularity in the arrangement of the teeth.
- (3) Poorly calcified enamel which showed pitting, grooving and pigmentation.

A diet of cereals—oatmeal, maize, white flour, rye or barley, especially the first of these, increased the severity of the defects. The anti-calcifying effect of cereals could be completely prevented by liberal allowances of cod-liver oil or irradiated ergosterol. Irradiation of the animals with the mercury vapor lamp exerted a less pronounced beneficial influence upon the tooth structure. Only slight benefit resulted from the addition of calcium to the vitamin D deficient diet, and perfect teeth were formed upon a low calcium intake provided that the allowance of cod-liver oil was liberal. On the other hand, when the vitamin D content of the diet was below the optimal value, calcium was found to enhance the beneficial effect. The addition of phosphorus to a diet either rich or deficient in vitamin D seemed to exert little effect upon tooth structure. These observations were taken to indicate that the mineral content of the diet was of minor importance as compared with the vitamin supply.

It was also shown that the teeth of the offspring were influenced by the diet of the mother during pregnancy. The deciduous teeth of puppies whose mothers during pregnancy and lactation had been fed diets deficient in vitamin D erupted late and were poorly calcified. The maternal influence was also seen in the permanent teeth, the latter being much less resistant to the ill effects of a deficient diet after weaning, if the puppies had been born of a mother which received a deficient diet during pregnancy and while she was suckling her pups.

Vitamin D was shown to have an important influence upon tooth repair in adult dogs. It is not possible to induce dental defects in full grown dogs by dietary means. When, however, a dog's tooth is filed at intervals of a few days it reacts to the injury by the formation of so-called secondary dentine. The amount and quantity of the new-formed dentine were found to be very favorably influenced by vitamin D administration; cereals were, on the other hand, detrimental. In none of the experiments upon puppies or adult dogs was actual caries produced. Yet, the effects upon tooth structure and repair resulting from vitamin D deficiency are undoubtedly pertinent to the question of the development of caries in man, since such defects would presumably prepare the way for bacterial invasion. In support of this assumption M. Mellanby has found from a histological examination of 1000 deciduous teeth and a large number of permanent teeth, that of those showing normal or nearly normal structure and good calcification 27 per cent showed carious cavities. Of teeth showing abnormal structure—hypoplastic teeth—85 per cent were carious. McCollum and his associates have also described "caries-like" lesions in rats fed upon low vitamin diets.

These observations conform with the trend of opinion

today, namely, that dental decay is due primarily to defect originating within the tooth itself rather than to local conditions within the mouth. The immediate cause of the erosion and decay of the tooth is, of course, bacterial invasion.

Direct evidence that the results of deficient diets are applicable to the question of human caries has been obtained by M. Mellanby. The results of investigations carried out upon English school children (6-10 years) are given in table 64.

The children were divided into groups. All received the same basal diet but the quantities of cereal and vitamin D were varied in the different groups. The teeth were examined and their state recorded at the beginning of the experimental period and again at the lapse of several months.

Taking the experimental results as a whole, the dietary factors influencing the development of caries, so far as this is the result of abnormalities of tooth structure may be summarized as follows, (a) the level of vitamin D intake or the degree of ultraviolet radiation (b) the proportion of cereal (anticalcifying) or the supply of calcium and phosphorus, though the latter factor would appear to be of secondary importance.

Tisdall and associates have obtained results which are, in the main, confirmatory of those of Mellanby. A definitely beneficial effect of vitamin D administration was demonstrated in children under the age of 10 years. The results obtained with older children were indecisive. Still more recent clinical research emphasizes the importance of vitamin D in the prevention of dental caries. In a group of school children given relatively large doses of vitamin D in the form of cod liver oil (800 units daily) over a period of eight months, dental caries was 65 per cent less than in the control group not receiving the vitamin. (McBeath and Verlin).

Some of the other conditions for which vitamin D has been advocated are, postoperative tetany, chronic arthritis, psoriasis and acne. In some of these conditions massive doses were used (up to 500,000 units) at a single dose. Such unphysiological dosage is not free from danger (p. 708).

VITAMIN E (ANTI-STERILITY)

Mattill and Conklin observed some years ago that rats reared upon a diet of whole milk were usually sterile. Evans and Bishop observed a failure of reproduction in rats (male or female), fed upon a diet consisting of casein, starch and lard and containing butter fat or cod-liver oil as well as the other known vitamins and essential minerals. The addition to the diet of lettuce, wheat germ, or alfalfa corrected the defect. It was therefore concluded that a hitherto unknown vitamin existed which was necessary for normal reproduction. This was termed vitamin E.

In male rats on a vitamin E deficient diet the loss of fertility is a progressive process. In the earlier stages of the vitamin deficiency the spermatozoa lose their motility; later they fail to be produced. Finally the spermatogenic epithelium degenerates and the sex instinct fails. In females, estrus occurs normally and when fertilization occurs the implantation of the ovum is not prevented but the embryos after developing for a short time die and are resorbed. The nature of the defect in embryological development leading to fetal death has been studied by Adamstone in chick embryos and hens on vitamin E deficient diets. He found that cell proliferation in the mesoderm forms a ring at the blastoderm stage which by strangling the blood vessels cuts the embryo off from its blood supply. Rarefaction of the mesenchyme and failure in the development of the blood-forming tissues is the principle abnormality seen in the embryos of vitamin E deficient rats.

In animals the administration of vitamin E, so it is claimed, even in the absence of any obvious deficiency, exerts an effect upon the reproductive functions. For example, wheat germ oil fed to rabbits is said to increase the size of the litters, and it has been asserted that cows previously sterile have passed through normal pregnancies after receiving large doses of vitamin E. Several observations point to vitamin E as playing an essential rôle in the metabolism of skeletal muscle, but though α -tocopherol is curative for the nutritional muscular dystrophy of rabbits, its administration in human neuromuscular disorders has not proved of benefit. Indeed, there is no proof that any clinical condition is due to a deficiency of this vitamin. Though earlier reports seemed to indicate that vitamin E in the form of wheat germ oil was of value in the treatment of sterility in women due to repeated miscarriages (habitual abortion), and though some support for such an action has been given by more recent work, full confirmation has not been secured. It does appear, however, that many pregnant women suffer from a deficiency of vitamin E.

It has been shown by Evans and his associates that vitamin E, or a principle closely related to it, has also a growth promoting action upon rats after the fourth month. The influence upon growth is not secondary to an effect of the vitamin upon the sex glands since it is evident after the latter have been removed. Other manifestations of vitamin E deficiency in rats are partial paralysis of the hind limbs, due to degenerative changes in the muscles, and loss of hair. These appear only

after a prolonged period (15 months) on diets low in vitamin E.

There appears to be a relationship between the pituitary and the thyroid and vitamin E. The potency of extracts of pituitaries of female rats on vitamin E deficient diets to induce ovulation in rabbits is reduced; the power is restored by the administration of vitamin E. Degenerative changes in the pituitary, involving both acidophil and basophil cells, have been described as resulting from a deficiency of this vitamin.

Chemical properties and sources

Vitamin E is soluble in fat and in the usual fat solvents. As in the case of the other fat-soluble vitamins D and K and carotene, bile in the intestine is necessary for its absorption. Its chief sources are green vegetables, e.g., lettuce, peas, alfalfa and the germ of various seeds. Wheat germ oil has a very high vitamin E potency and most ordinary vegetable oils contain it in fairly large amounts. It is absent from the endosperm of wheat (white flour).

Vitamin E is a higher alcohol with the formula $C_{29}H_{50}O_2$. It is not a single compound but like vitamin D is multiple in nature, the different compounds with vitamin E activity being known as *tocopherols* (tokos = childbirth, phero = I bear). Three physiologically active, crystalline isomeric compounds—*alpha*, *beta* and *gamma tocopherols*—have been obtained by Evans and his associates from vitamin E concentrates of wheat germ oil. α -tocopherol, which alone is present in lettuce oil, has much the highest potency of the three. The tocopherols are associated in nature with anti-oxidative agents, i.e., substances which inhibit the oxidation and consequent rancidity of certain oils and fats. This antioxidative property of substances rich in vitamin E does not run parallel with their biological activity so is apparently not due to vitamin E itself. Vitamin E is very susceptible to oxidation and rapidly loses its activity in the presence of fats and oils undergoing oxidation, a fact which is made use of in preparing E-deficient diets, an oil or fat such as cod-liver oil or lard on the verge of rancidity being added in order to destroy the last trace of vitamin E activity. From their antioxidative properties and the similarity of their absorption spectra it was suspected that tocopherols and hydroquinone were closely related chemically. This suspicion was substantiated by the identification by Fernholtz of durohydroquinone among the decomposition products of α -tocopherol when subjected to heat. α -tocopherol was later synthesized by Karrer and his colleagues,

and by Smith, Ungnade and Pritchard from trimethylhydroquinone and phytylbromide. The following structural formula has been proposed for it by Fernholtz:

α -tocopherol

The effect of vitamin E in enhancing the action of vitamin A has been mentioned (p. 636).

VITAMIN K, THE ANTIHEMORRHAGIC OR COAGULATION VITAMIN

Chicks, young geese and ducklings upon diets lacking in green stuff are subject to a fatal hemorrhagic disease which, as a result of the work of Dam and his associates, has been shown to be due to vitamin K deficiency. It has been established by these and other workers that the bleedings are due to a reduction in the prothrombin concentration of the blood (see p. 91). The low value of this essential factor in the clotting mechanism leads to a prolonged coagulation time. Green leaves, especially alfalfa and other clovers, spinach, cauliflower and cabbage, are rich sources of vitamin K; cereals, carrots, yeast and wheat germ contain it in minimal amounts, while little or none is present in potatoes, mangolds or cod-liver oil.

It has not been found possible to induce a hemorrhagic tendency in any mammal so far investigated—guinea pigs, rats, hogs or dogs—by feeding K-free diets alone. No hemorrhagic disease in man, so far as is known, is due to lack of

degree than occurs in the intestines of birds; or better absorption. Bile, as shown by Grea and Schmidt, is necessary for the absorption of vitamin; in animals with bile fistulae and in

structive jaundice in man, failure of the vitamin to be absorbed is the cause of the bleeding tendency associated with these conditions. The administration of vitamin K concentrates combined with bile salts is corrective (see also p. 466). Not only obstructive jaundice but any condition which interferes with the absorption or utilization of the vitamin may result in K deficiency and a tendency to bleed. Thus in sprue and other states associated with defective fat digestion and absorption in biliary or gastrocolic fistula or in some liver diseases, vitamin K lack may be encountered. The hypoprothrombinemia induced by dicumarol (p. 90) or by salicylic acid, and the hemorrhagic tendency of the new-born are counteracted by the administration of vitamin K.

Chemistry

McKee and his associates in 1939 isolated vitamin K from alfalfa (called K_1) and from putrefying fish meal (K_2). Later K_1 was synthesized by Binkley and by Fieser and their associates. It is 2-methyl-3-phytyl-1,4-naphthoquinone and has the following formula.

Vitamin K_1 (2-methyl-3 phytyl-1, 4-naphthoquinone)

vitamin K in the diet. Almquist and Stockstad have shown that some synthesis occurs in the intestine of chicks as a result of bacterial action,³ and it seems established that the immunity of man and other mammals listed above to a dietary lack of vitamin K is due either to synthesis in greater

Vitamin K_1 is fat-soluble; it is contained in the unsaponifiable fraction of the alfalfa lipids. Vitamin K_2 is similar chemically and in its physiological action to K_1 but possesses only 60 per cent of the latter's potency. Several other naphthoquinone compounds have been shown to possess vitamin K activity. One of these was isolated in 1933 by

³ For footnote see page 650.

Anderson and Newman from tubercle bacilli and later synthesized, but it was not until 1939 that its antihemorrhagic property was demonstrated by Almquist and Klose. This substance (sometimes called phthiocol) is 2-methyl-3-hydroxy-1,4-naphthoquinone. Other naphthoquinone compounds have since been investigated. Of these 2-methyl-4-naphthoquinone is the most powerful anti-hemorrhagic factor known, being two or three times more potent than K_1 . It differs from the latter chemically only in that it does not contain the phytyl group; the latter would appear therefore to be of no importance in so far as physiological activity is concerned. Water-soluble synthetic naphthoquinone derivatives have been prepared. Some of these can be given orally without bile salts or intravenously, which of course is a decided advantage.

THE MEASUREMENT AND STANDARDIZATION OF VITAMIN POTENCIES

The general principle employed in testing a food material for its content in a given vitamin is as follows. An animal e.g., rat, guinea-pig, etc., susceptible to deprivation of the vitamin to be tested is placed upon a diet which lacks that vitamin but is otherwise adequate. The substance containing the vitamin is added to this basal diet and the amount which is required to prevent the appearance of the effects characteristic of a lack of the vitamin under test (preventive test) or the amount required to correct the effect after it has appeared (curative test) is noted. In most cases the preventive test is employed. The minimal daily quantity of the food material required is said to contain 1 unit of the vitamin. For example, in testing vitamin A, a group of young (21–29 days old) healthy rats are placed upon a diet of purified casein, cornstarch and containing suitable amounts of brewer's yeast to furnish vitamins B_1 and B_2 and of irradiated ergosterol as a source of vitamin D. A suitable amount of a mixture containing the essential minerals Ca, P, K, Na and Fe, is added. Vitamin A is completely excluded. Another group of rats is placed upon this diet but containing, in addition, weighed amounts of the food to be tested, e.g., butter, fat, green vegetable or other material. After a short time (4 weeks or so) growth ceases in the first group of rats and the first eye symptoms appear. The minimal quantity of material required to be fed to the second group for the prevention of these effects and to cause a gain in growth of 3 grams per week is said to contain 1 unit of vitamin A. The content of vitamin A in the various foods may therefore be expressed as the number of units per gram, per ounce or per pound; or per 100 calories. Thus, a good sample of butter contains about 22,500 units per pound and 700 units per 100 calories, whereas lettuce contains

only 2400 units per pound but on account of its low calorie value, some 2775 units per 100 calories. Similar methods are employed for the measurement of the vitamins B_1 , C, D and E. The prevention of arrested growth being the criterion used for estimating B_1 , the prevention of scurvy in guinea pigs the criterion for C and for vitamin E the power to restore fertility in a female rat in which a series of previous resorptions has occurred. In the measurement of vitamin D, young rats (40–70 grams in weight) are deprived of ultraviolet irradiation and placed for 3 or 4 weeks upon a special rickets-producing diet, i.e., one with a high Ca:P ratio⁴ and lacking in the antirachitic vitamin. A unit of vitamin D is taken as the daily amount which will prevent (preventive test) or will cure the condition after it has appeared (curative test). Evidence of the

FIG. 259. Diagram of a longitudinal section through a grain of wheat, showing B pericarp, forming the branny envelope; A, aleurone layer of cells forming the outermost layer of the endosperm removed with the pericarp during milling; E, parenchymatous cells of the endosperm; G, embryo or germ. (From *Med. Res. Council Rep.* 1932, No. 167.)

existence and extent of the disease or of the degree of healing is obtained by (a) X-ray examination, (b) analysis of the bones of their ash content or (c) by means of the "line test." Determination of the ash content or examination of the bone by means of the line test involves the sacrifice of the animal, the former method being used in the preventive test, the latter in the curative test. By X-ray examination the extent of healing under vitamin D administration can be followed in the same animal. It may be used either in a preventive or a curative test.

⁴ Steenbock's rachitogenic diet is as follows:

	%
Ground yellow maize.....	76
Wheat gluten.....	20
Sodium chloride.....	1
Calcium carbonate.....	3

Its Ca:P ratio is 4 to 1.

The "line test" depends upon the fact already alluded to p. 653 that the end of the severely rachitic bone is mineral-free. When healing commences lime salts are deposited. In the employment of this test the animals are kept upon a rachitogenic diet until severe rickets has developed. A measured dose of the material containing vitamin D is then administered daily. At the end of 10 days the animals are killed and the ends of the tibiae are split longitudinally and immersed in a 1.5 per cent solution of silver nitrate. If calcium phosphate is present in the metaphysis of the bone, silver phosphate is formed which upon exposure to light is reduced to metallic silver which causes a dark band to appear; the test is then designated as "positive" (+). In the absence of healing the bone end remains unchanged in color; the test is then said to be "negative" (-). The degree of healing may be gauged from the depth of the darkened band, and is usually expressed by the signs +, ++ or +++. A colorimetric method for the determination of vitamin D can be employed. The reagent is antimony trichloride and acetylchloride in chloroform. It reacts with the vitamin to give a yellowish pink color.

Riboflavin possesses the property of fluorescence. Upon this is based the fluorometric method of assay, the estimation being made upon solutions of the vitamin by means of a fluorophotometer. An animal assay method, based upon the general principles outlined above, or a microbiological method, is also available. The growth response to the vitamin of *Lactobacillus casei* is the basis of the latter method. For the assay of *nicotinic acid* either a colorimetric or a microbiological method may be used. The former method is based upon the yellow color produced by the reaction of pyridine with an aromatic amine in the presence of cyanogen bromide. The microbiological method depends upon the effect of nicotinic acid upon the growth of cultures of the dysentery bacillus. A colorimetric and a microbiological method are also available for assaying *pyridoxin*. The colorimetric method is based upon the color which appears when pyridoxin is acted upon by diazotized sulphanilic acid and p-nitroaniline in an alkaline medium. The microbiological method employs the fact that yeast cells or lactic acid bacilli grow only in the presence of pyridoxin. A rat growth method can also be used, in which rats are fed a basal diet complete in all respects except that it lacks pyridoxin. Other methods of pyridoxin assay are the curative and preventive methods based upon the development of acrodynia in rats. *Pantothenic acid* may be assayed by the chick-growth test or by the growth response of certain bacteria, e.g., *Proteus morganii* or *Lactobacillus casei*.

A reliable chemical method has been developed for the assay of vitamin C, based upon its high reducing power. The vitamin C content of a material is es-

timated from the reduction (decoloration) of the 2,6-dichlorophenolindophenol. For the detection of vitamin C deficiency clinically either the capillary sistance test (p. 95) or the intradermal test may be used. The intradermal test consists of injecting a solution of 0.0025 M dichlorophenolindophenol. The dye is decolorized in 10 minutes in subjects well supplied with vitamin C but not for 13 minutes or more in those suffering from a deficiency of vitamin C. The vitamin concentration of the plasma also may be employed in the saturation test (pp. 647 and 648).

Vitamin K may be assayed by the curative method of Almquist and Klose. This is based upon the fact that the clotting time of vitamin K deficient chicks becomes normal within three days after their being placed upon an adequate diet.

Owing to the confusion which has arisen from the employment by various workers of different standards for measuring and expressing vitamin potencies the Commission on Biological Standardization of the League of Nations has recommended the following vitamin units for international usage.

- (1) Vitamin A unit = The vitamin A activity of 0.6 microgram (0.6 γ) of pure β -carotene prepared from carrots by Willstätter's method. (This is from $\frac{1}{10}$ the amount required daily to cure xerophthalmia and restore growth in the rat.)
- (2) Vitamin B₁ unit = The antineuritic activity of 10 mg. of a standard adsorption product of the vitamin prepared from an extract of rice polishings. Twenty to thirty mg. daily of this preparation will cure polyneuritis in a pigeon (300 grams) on a diet of polished rice.
- (3) Vitamin C unit = The vitamin C activity of 0.05 cc. l-ascorbic acid. This is about $\frac{1}{10}$ the quantity required daily to prevent scurvy in a guinea-pig on a scorbutic diet.
- (4) Vitamin D unit = Antirachitic activity of 0.025 microgram (0.025 γ) of crystalline vitamin D (calciferol). This amount given daily for 8 days to a rachitic rat causes a broad band of calcification in the metaphysis of the proximal end of the tibiae.

CHAPTER LVII

DIETARY REQUIREMENTS

In planning a diet the following requirements must be taken into account.

- (1) The total caloric value.
- (2) The proportion of the different foodstuffs—carbohydrate, fats, and protein.
- (3) The mineral constituents.
- (4) The vitamin content.

In order that the body shall not be forced to consume its own tissues for fuel, the caloric value of the ingested food for 24 hours must balance the heat eliminated by the individual during the same period. The basis for computing the latter value is the basal metabolic rate plus an allowance for the energy expended in performing work. The basal metabolic rate is obtained by direct determination (p. 533) or by calculation from the subject's height and weight (p. 534).

The following table gives the average extra caloric allowances for different grades of muscular activity:

	Calories
Sedentary life.....	800- 900
Light work, e.g., professional and business men.....	900-1400
Moderate work, e.g., mechanics.....	1400-1800
Heavy work, e.g., laborers, athletes, etc.....	1800-3500

SAMPLE CALCULATION OF CALORIC REQUIREMENT.

A young average-sized man (surface area 1.8 square meters) has a basal metabolism of $(1.8 \times 40 =) 72$ calories per hour, or a total of $(72 \times 10 =) 1152$ calories for the 16 hours that he is awake. During sleep the metabolism is 90 per cent of the basal value. So $(\frac{90}{100} \times 72 \times 8 =) 518$ Calories would be his energy requirement for 8 hours of the day. Apart from that required for work his total daily requirement is therefore $(1152 + 518 =) 1670$ Calories. To this is added the appropriate work allowance given in the table above which will bring the total up to from 2500 to over 5000 calories. An allowance of 6-7 per cent is made to cover the increased metabolism due to the food itself (specific dynamic action, p. 554). These calculations are given in tabular form below.

	Calories
Basal metabolism (16 hours).....	1152
Metabolism of sleep (8 hours).....	518
Allowance for light work.....	1200
	2870
6 per cent for S.D.A.....	172
Total.....	3042

The actual caloric values of various foodstuffs are given in table 65. See also table 45, p. 536, for the energy requirements for different types of exercise. The effect of climate upon the metabolism must also be taken into account, a higher energy intake being required in cold and temperate climates than in the tropics.

THE RELATION OF AGE AND SEX TO THE CALORIC REQUIREMENT

Women have a somewhat lower basal metabolic rate (p. 534) than men and generally speaking they expend less energy in muscular work; their food requirement is proportionately less.

Children require weight for weight a greater food allowance than the average adult for three reasons. (a) Their basal metabolic rate is considerably higher especially at the younger ages. (b) A proportion of the food material is utilized for building body tissue. (c) Children, as a rule, expend more energy in muscular activity than the average adult. For example, a boy of 16 years of age, of average physique and taking an active part in games requires a daily energy intake equal to that of a man—from 3000 to 4000 Calories or from 50 to 70 Calories per kilogram of body weight per day (average adult requirement 46 Calories per kilogram). When growth is very rapid an even larger allowance may be required. The food requirement of a girl of from 16 to 18 years of age is approximately that of a full-grown woman though of course size, rate of growth and the amount of exercise which she takes are modifying factors. During the first two years of life the daily dietary requirement amounts to about 100 Calories per kilogram (45 Calories per pound) of body weight and from the second to the fourteenth year to about 80 Calories per kilogram.

The relative caloric requirements at different ages are shown in table 66, the requirement of the average man, i.e., one having an energy expenditure of 3000 Calories being taken as unity. In computing the food requirements of a household this is referred to as the "man value." As a first approximation the other members of the family are apportioned calorie allowances in accordance with the figures shown in the table. Thus, the mother's allowance would be 0.83 of a "man value"

TABLE 65

Average composition and energy values of edible portions of some common food materials

	PER CENT					ENERGY VALUE	
	Water	Protein N × 6.25	Fat	Carbo- hydrate	Ash	Per kg.	Per pound

Child 6 to 7½.....	0.60
Child 3 to 5½.....	0.50
Child 2 to 2½.....	0.40
Child 1 to 1½.....	0.30
Child up to 1.....	0.20

about 2500 calories, whereas a boy of 14 years of age would receive 3000 Calories.

THE PROPER PROPORTIONS OF THE THREE FOOD-STUFFS IN AN ADULT DIET

In a diet having a total energy value of about 3000 calories the amounts and percentages of its three main constituents are as follows.

	GRAMS	CALORIES	PER CENT OF TOTAL CALORIES, APPROXIMATE
Carbohydrate.....	380	1440	48
Fat.....	133	1200	40
Protein.....	90	360	12

Cereals and other carbohydrate foods contain a large proportion of water. Lean meat is about 75 per cent water, whereas fats and oils are highly concentrated foods, being for the most part water free. It will also be recalled that weight for weight fat has more than double the caloric value than that of pure carbohydrate or protein. Over 70 per cent of the protein intake of the adult should be made up of proteins of first class biological value (p. 559). In the diets of persons living in northern climates the calories derived from fat may constitute 45 per cent or more of the total.

The protein allowance

A great deal of controversy has centered around the question of the protein requirement of the adult. Chittenden some years ago made a study of the subject in a series of experiments upon himself and groups of students, soldiers and athletes. He showed that nitrogen equilibrium

could be maintained upon a total daily intake of 25 grams or less of first class protein.¹ Upon an ordinary mixed diet containing proteins of varying biological values nitrogen equilibrium was established on an allowance of between 40 and 50 grams for a man of average weight (70 kgm.). This is from 0.6 to 0.7 grams of protein per kilogram. Chittenden claimed that the larger protein intake of 120 grams considered by previous observers (e.g., Voit) were unnecessary, if not actually deleterious to health. It was contended that the renal work entailed in the excretion of large quantities of nitrogen was conducive to kidney disease. Many other ills were ascribed to the excessive consumption of protein. He also reduced the total energy intake to around 2000 calories and stated that the more liberal diets were dictated by appetite rather than by physiological necessity. His subjects, he claimed, could carry out their usual activities just as well upon such a diet and enjoyed better health than they had, previously, upon their customary fare.

Since nitrogen equilibrium can be established upon a protein intake of around 40 grams per day, it would seem unnecessary to give more. The excess amount must obviously be catabolized to furnish energy, which can be furnished more economically by non-nitrogenous food, or be simply stored as carbohydrate or fat. The weak point in this argument is, as many critics of the low protein dietary have pointed out, that the ability of the body to adapt itself for a few months to a restricted protein intake is not proof that such constitutes the physiological optimum. It has also been pointed out that custom has dictated for persons in temperate climates a higher protein intake than Chittenden's standard. Pearl has estimated that the average daily protein intake per person of the population of the United States is around 120 grams. Even the diets of the Japanese and of the hardier races of India, according to McCay, contain a greater quantity of protein than that recommended by Chittenden. McCay observes that tribes in India who are accustomed to diets with the higher protein content are healthier and of better physique than those subsisting upon a more restricted protein intake. The investigation of Orr and Gilks also seems to show clearly the value of a generous protein allowance. Their report is based upon a study of two African tribes, the

¹ We have already seen that the daily urinary excretion of N on a nitrogen-free diet but of adequate calorie value is around 3 grams (p. 552). This represents the catabolism of 18.75 grams (3 x 6.25) of tissue protein.

Masai and the Akikuyu, who though living side by side eat quite different diets. The diet of the Masai has a high protein content; it consists largely of meat, milk and blood. They obtain the latter from the living animal by piercing its jugular vein with an arrow. The Akikuyu live upon a vegetarian diet composed of cereals (chiefly maize) legumes, plantains, sweet potatoes and other tubers, and green leaves. The members of the meat-eating tribe are some 5 inches taller and 50 pounds heavier than the vegetarians, and their muscular power is about 50 per cent greater. The Masai are comparatively free from disease, whereas bone deformities, dental caries, anemia, pulmonary diseases and tropical ulcer are prevalent among the Akikuyu. Arthritis, however, was found to be much more common among the Masai. Though these tribes come of different original stocks there is a considerable amount of intermarriage, and the differences between them in physique and health appear to have a dietary rather than a racial basis.

Such facts suggest that, in furthering the well-being of the body, protein probably plays an important part which is not revealed by short term experiments based upon the study of nitrogen balances. There are indications that physical fitness and resistance to disease are associated with the higher protein intakes. It may be that it is only by supplying a comparatively large quantity of protein in the diet that certain vital tissues, e.g., ductless glands, can obtain adequate amounts of essential amino-acids to carry out their functions at the highest state of efficiency. There is little evidence, on the other hand, that a high consumption of protein causes renal or other diseases. Thomas records that the Greenland Eskimos are almost exclusively carnivorous, consuming enormous quantities of meat (and fat) yet renal and cardiovascular disease is not common among them.

However, it has been shown by Smadel and Farr that the level of protein in the diet of rats has a pronounced influence upon the course of experimental nephritis. In animals upon a low (5 per cent) protein diet the disease ran a much more favorable course than in those upon a diet containing a large proportion of protein (40 per cent). Nephritis in animals has also been reported to follow very high protein intakes, but the levels are far above anything possible in human dietaries.

It now appears that the true protein requirement for the average man lies about mid-way between the two extremes of Chittenden and the older observers. This is from 70 to 100 grams,

i.e., somewhat more than 1 gram per kilogram body weight. In an extensive investigation carried on over a period of six years upon some 400 medical students living on diets of their own choice, Beard found that the average daily excretion of nitrogen in the urine was about 11 grams. This (after allowance was made for the loss of nitrogen in the feces) was calculated to represent the consumption of approximately 77 grams of protein, i.e., approximately 1.1 gram per kilogram. In a nutrition survey in a suburb of Toronto undertaken by Ferguson and McHenry upon a large number of school children, the daily consumption of protein was 75 grams for girls aged from 16 to 20 years, and 100 grams for boys of the same age group.

Growing children require, in proportion to their weight, a considerably greater protein allowance than do adults. Up to 1 year about 16 per cent of the total Calories of an artificial diet should be furnished by protein (4 grams per kilogram of body weight).² The protein requirement falls gradually until the sixth year when it amounts to about 13 per cent (2.6 grams per kilogram) of the total Calorie requirement. This value is maintained to the end of the period of growth. Children also require a higher proportion of proteins of high biological value (p. 558) than do adults. In young infants high grade proteins should constitute about 100 per cent of the protein allowance (as in milk); at 1 year over 90 per cent, and up to 5 years over 60 per cent. From the latter age to adolescence the proportion should not be far from 50 per cent, and in adult life at least 35 per cent.

Persons undertaking heavy work, undergoing muscular training, or convalescing from wasting diseases also require a more liberal protein allowance. In rigorous climates, protein food, on account of its specific dynamic action, is in higher demand than in warmer localities.

The indispensability of fat

Since body fat can be derived from carbohydrate food it might be thought that dietary fat could be dispensed with. On the contrary, fats quite apart from the fact that they furnish fat-soluble vitamins, are essential elements in nutrition.

Fatty foods contain, besides neutral fats, and fat-soluble vitamins, certain fatty acids which are essential for health and which cannot apparently be synthesized in the body. Rats placed upon a

² In mother's milk the protein calories amount only to 11 per cent of the total. The protein is, however, of higher quality than that of cow's milk.

low fat diet, but containing all the known vitamins, after a time cease to grow but growth is resumed when the essential fatty acids, even in small amounts, are added to the diet. Saturated fatty acids (e.g. oleic) or the animal's own body fat formed from carbohydrate have no protective action. Other effects on rats resulting from a deficiency of the essential fatty acids are, scaliness of the skin, caudal necrosis, emaciation, kidney lesions and early death. The group of *unsaturated fatty acids* which are essential for normal growth and nutrition includes *linoleic* (with 2 double bonds), *linolenic* (3 double bonds) and *arachidonic* (4 double bonds). Actually, only one of these fatty acids is essential, for, as with certain amino-acids, they can replace one another in the diet to a greater or less extent. In fat-deficient animals, the blood lipids have an abnormally low iodine number. In hogs on a low fat diet the linoleic acid content of the lard may be only 1.2 per cent as against a normal of 7 per cent. Puppies upon a diet low in fat develop a scaly or eczematous condition of the skin that is readily cured by feeding lard or other fats. The serum lipids show an iodine number about 25 per cent below normal. It is thought that certain eczematous conditions in the human subject are due to fatty acid deficiency. These subjects show a low content of unsaturated fatty acids in the blood lipids, and babies kept for several months upon a diet very low in fat developed a generalized eczema which was corrected when the fat of the diet was restored. During the period of low fat feeding the iodine number of the serum lipids of these infants was depressed. (See Burr and associates.)

On account of their high energy value fatty foods are demanded in relatively large amounts by men performing very heavy work, especially in cold climates. A pound of beef fat, which contains little water, yields about 4000 calories. The caloric value of an equal amount of white bread, which contains over 40 per cent of water, is only about one-quarter of this. Fat pork, beans and peas (vegetables relatively rich in fat) are prominent items in the diet of Canadian lumbermen and construction workers. The daily energy expenditure of some of the former workers may run to 8000 calories. Another advantage of fat is its superior "staying power." Its digestion and absorption are extended over a much longer period than those of carbohydrates. Hunger, "emptiness" and fatigue are experienced much sooner upon a diet high in carbohydrate than upon one containing a

liberal allowance of fat. The actual efficiency of fat as a fuel for muscular work as shown by Krogh and Lindhard (p. 621) and by Murlin and Marsh is only from 10 to 12 per cent less than that of carbohydrate.

Children, especially those under the age of 1 year, require a larger proportion of fat in the diet than do adults; Holt and Fales place the daily requirement at about 4 grams per kilogram up to the age of 1 year (from 35 to 40 per cent of the total calories) with a gradual reduction to about 3 grams per kilogram at 6 years. According to these

* Tentative goal toward which to aim in planning practical dietaries; can be met by a good diet of natural food. Such a diet will also provide other minerals and vitamins, the requirements for which are less well known.

- † 1 mg. thiamin equals 333 I.U.; 1 mg. ascorbic acid equals 20 I.U.
- ‡ Requirements may be less if provided as vitamin A; greater if provided chiefly as the pro-vitamin carotene.
- § Needs of infants increase from month to month. The amounts given are for approximately 6-8 months. The amounts of protein and calcium needed are less if derived from human milk.
- ¶ Allowances are based on needs for the middle year in each group (as 2, 5, 8, etc.) and for moderate activity.
- ** Vitamin D is undoubtedly necessary for older children and adults. When not available from sunshine, it should be provided probably up to the minimum amounts recommended for infants.

Further Recommendations, Adopted 1942:

The requirement for *iodine* is small; probably about 0.002 to 0.004 milligram a day for each kilogram of bodyweight. This amounts to about 0.15 to 0.30 milligram daily for the adult. This need is easily met by the regular use of iodized salt; its use is especially important in adolescence and pregnancy.

The requirement for *copper* for adults is in the neighborhood of 1.0 to 2.0 milligrams a day. Infants and children require approximately 0.05 per kilogram of bodyweight. The requirement for copper is approximately one-tenth of that for iron.

The requirement of *vitamin K* is usually satisfied by any good diet. Special consideration needs to be given to newborn infants. Physicians commonly give vitamin K either to the mother before delivery or to the infant immediately after birth.

In childhood and in pregnancy (especially in the later months) and in lactation the calcium requirement is higher than that given above. For children of from 3 to 20 years the minimum is placed at 1.0 to 1.4 gram per day. In the later months of pregnancy when from 20 to 30 grams of the

mineral are being deposited in the fetus, the daily allowance should be at least 1.5 gram; 2 grams should be the daily allowance during lactation. The best source of calcium for the growing child is milk, which contains about 1.3 grams per quart. Cereals also are rich in calcium though much of it is not available; meat contains insignificant amounts of this element (see table 67). Milk and other dairy products are good sources of available phosphorus. Though cereals and many vegetables contain this element in much larger amounts the greater proportion of it is not utilized (p. 711). Egg yolk, meat, liver and kidney, certain vegetables, fruits and nuts are the main sources of iron. Milk is very poor in this element.

The daily requirement of iron for children is about 0.5 milligram per kilogram of body weight; milk-fed infants therefore tend to develop anemia (p. 63) after the fourth month or so unless given iron in inorganic form.

Protein foods are rich in phosphorus, and so long as the diet contains a sufficient quantity of protein and is well balanced in other respects, no special

attention need be given to the phosphorus content of the diet. Phosphorus deficiency is seen in farm animals fed upon the produce of soils deficient in this mineral.

The basic elements, sodium, potassium and magnesium, are derived chiefly from cereals, fruits and vegetables. Sodium chloride is also taken in the form of cooking and table salt. The average daily intake is from 10 to 12 grams. Many preparations of table salt are also sources of iodine, since it has become the custom of the manufacturer to add minute quantities of this element to his product. The daily iodine requirement for adults is from 0.15 to 0.30 milligram.

The dietary allowances recommended by the food and nutrition board of the National Research Council, Washington, are given in table 67a. Some of the allowances, especially those for thiamin and ascorbic acid, may be unnecessarily high. Dietary surveys indicate that good nutrition is maintained upon intakes of these vitamins with values less than half those given in the table (see Riggs and associates and Ferguson, Leeson and McHenry).

SECTION VII. THE DUCTLESS GLANDS OR ENDOCRINES

CHAPTER LVIII

INTRODUCTION. THE THYROID GLAND

DEFINITIONS. NATURE OF HORMONES. METHODS OF INVESTIGATING ENDOCRINE FUNCTION

(The products of the ductless glands—thyroids, adrenals, pituitary, etc.,—belong to a class of physiologically active chemical substances known as *internal secretions or hormones*.) The latter term was first used by Bayliss and Starling in the report of their discovery of secretin (p. 451), it is derived from a Greek word meaning to excite. Though nearly all the actions of the secretions of the ductless glands are excitatory in character a few internal secretions (e.g., enterogastrone, p. 436) are inhibitory. The term *chalone* has been suggested for the latter by Schafer but is not often used. (A hormone may be defined as a chemical substance which, having been formed in one part of the body, is carried in the blood stream to another organ or tissue and influences its activity.) With the exception of the secretions of the thyroid, gonads and adrenal cortex, the various hormone preparations which so far have been obtained by extraction and employed in medicine, are almost or quite inert when administered orally. Even though the sex hormones and the principles of the adrenal cortex are effective by oral administration, the dose when given in this way must be much larger than if given parenterally in order to produce the same response. Adrenaline, insulin and the principles of the parathyroids and pituitary, in order to be effective, must be given by injection. Most of the ductless glands are present in all orders of vertebrates and an extract obtained from the gland of one order exerts, as a rule, its specific effect when administered to a member of another order, e.g., the hormone of the sheep's thyroid influences the growth and development of frog larvae (tadpoles). (See also p. 671.)

Apart from small amounts which may be held in the endocrine organs themselves, hormones are not stored in the body. Therefore, in cases of endocrine deficiency, repeated small doses rather than large doses at infrequent intervals are required to correct the deficiency. A hormone does not stimulate the gland which secretes it. Thyroid extract, for example, does not stimulate the

thyroid; and the ovarian hormones do not stimulate the ovary directly.

Three main methods are available for the study of an endocrine function. *First*, an extract of the gland tissue may be prepared which may then be injected into animals and a study made of its effects. *Secondly*, a particular gland may be removed from an animal and the subsequent life history of the animal watched, careful notice being taken of its subsequent development, growth, or any unusual symptom. Or, *thirdly*, studies may be made upon human subjects in whom one or other gland is known to be deficient or overactive.

A few words may be written here concerning the general chemical nature of the active principles of the endocrines. The hormones of the sex glands and adrenal cortex are steroids and closely allied in chemical structure, while the active principles of the pituitary, thyroid and parathyroids are proteins.

THE THYROID

Development, histology, blood and nerve supply

Very early in its evolutionary history the thyroid had a digestive function, a function lost long since but which its ontogeny recalls. The gland is developed from a single median outgrowth of hypoblast derived from the ventral wall of the primitive pharynx at the level of the 1st visceral cleft. This extends downwards. Its lower end bifurcates and enlarges to form the isthmus and lateral lobes of the thyroid. Its upper end gives rise to the foramen cecum of the tongue. The intervening portion—the *thyro-glossal duct*—normally disappears but sometimes persists and may give origin to accessory thyroids or to the so-called thyro-glossal cysts.

The *thyroid tissue* is composed of cuboidal epithelial cells arranged in a single layer around spaces roughly circular in shape and fairly uniform in size. These spaces, variously known as *vesicles*, *acini* or *alveoli*, contain a homogeneous gelatinous material—the *colloid substance*—which is the stored secretion of the gland. Connective tissue fibers support the alveolar walls and form septa which divide the gland into smaller masses. The cells lining the alveoli contain numerous mitochondria and a well defined Golgi apparatus. When the gland becomes active the Golgi apparatus hyper-

trophies and droplets of colloid appear in its proximity. The maximal normal weight of the human thyroid is, according to Marine, from 20 to 35 grams or around 0.4 gram per kilogram of body weight. The thyroid tissue of the early fetus consists of masses of epithelial cells showing little or no arrangement into acini. The latter appear about the 4th month but are small and contain little colloid.

The *blood supply* comes from the superior and inferior thyroid arteries, chiefly the former. The blood flow is profuse, the blood passing with little resistance from the arterial to the venous side through a wide capillary bed. The flow amounts to from 3.5 to 6 cc. per gram of tissue per minute, or about 5 liters per hour for the whole gland. The gland is richly supplied with *lymphatics* which drain lymph spaces surrounding the vesicles.

The *nerve supply* of the thyroid is derived from the vagus and the sympathetic. The sympathetic fibers leave the spinal cord between the 2nd and 5th thoracic segments and pass to cell stations in the superior and middle cervical ganglia, whence they are relayed to the gland through the superior laryngeal nerves and along the blood vessels. It is probable that the thyroid nerves are purely vasomotor in function and influence the activity of the gland indirectly, namely, by altering its blood supply. Control of thyroid activity is exerted mainly, if not exclusively, by the thyrotropic hormone of the pituitary (p. 725).

AN OUTLINE OF THYROID FUNCTION

Some of the first experiments upon the thyroid were performed in 1856 by Schiff who found that in dogs death followed its removal; from the symptoms preceding death it is now apparent that this was due to removal of the parathyroids (p. 700). As in the case of some other ductless glands, clinical observations gave the first hint concerning the functions of the thyroid. Hilton Fagg in 1871 reported a case of *cretinism* (p. 673) and ascribed it to absence or atrophy of the thyroid. Three years later Gull described the condition which today is known as *myxedema* or *Gull's disease*, but called it the *cretinoid state in adult life*. Horsley some years later removed the gland from monkeys and produced conditions resembling human cretinism and myxedema. Later experiments upon other species have established the fact that the thyroid secretion is absolutely necessary for the normal growth and development of young animals, and for maintaining the normal level of metabolism of animals of all ages. Magnus-Levy in 1895 demonstrated that thyroid deficiency was associated with a greatly reduced metabolism and that treatment with desiccated thyroid restored the metabolic rate to the normal level or above. Com-

plete thyroidectomy reduces the basal metabolic rate by from 40 to 45 per cent in about 8 weeks after the operation. Thyroidectomy in lambs, young rabbits, goats or calves has been shown to cause retarded skeletal growth and arrested sexual development (fig. 260). Apathy, lack of vigor, thickening of the skin, and a striking reduction in basal metabolism result in both young and full-grown animals. In young cattle increase in bulk but not in height is a notable feature; the animals appearing short-legged and of a broad, stocky build. Other effects of thyroid removal in the young are; delay in the ossification of the epiphyses of the long bones; poor growth of hair; failure in thymic involution; and subnormal intelligence.

FIG. 260. Triplet kids. Center animal normal; right- and left-hand animals thyroidectomized at 20 days old. Photograph taken 13 weeks after operation. (After Sutherland Simpson.)

The administration of thyroid extract to young animals shortly after thyroidectomy prevents these otherwise inevitable results. In full-grown animals the effects of thyroid removal can be corrected by thyroid administration at any time after operation.

The effects produced upon lower orders by thyroid removal and by thyroid feeding are even more striking. Gudernatch removed the thyroids from tadpoles, keeping a number of young animals of the same hatching as controls. The thyroidectomized larvae grew somewhat larger in size but did not metamorphose, though the controls developed into frogs within the usual time (fig. 261). Metamorphosis of the thyroidless creatures could be induced to proceed at the normal rate by thy-

roid feeding.¹ Also, the time required for the normal larvae to metamorphose completely could be shortened (from 104 to 20 days) by feeding thyroid tissue. Swingle has shown that inorganic iodine alone will produce similar effects. The effect of the thyroid hormone upon the axolotl is extraordinary. This animal is allied to the frog, but is purely aquatic in its habits. It has, in its adult form, a finned tail, gills and four short limbs, resembling somewhat an enormous tadpole which has undergone partial metamorphosis. Thyroid feeding causes the axolotl to lose its fin and gills, develop air breathing organs and forsake the aquatic life for which nature had designed it. See also pages 683 and 726.

FIG. 261. The effect of the removal of the thyroids upon the development of tadpoles A, thyroidless tadpoles. B, normal frogs of the same age as A. (After Allen, redrawn.)

In growing birds (chicks) and mammals, a stimulating effect of the thyroid hormone on growth has been demonstrated. Acceleration of growth has also been observed in a twin child suffering from hyperthyroidism.

THE RELATION OF THE THYROID TO THE PITUITARY, ADRENALS AND GONADS

The thyroid-pituitary relationship is considered in Chapter LXI. A relationship between the thyroid and adrenals is indicated by the following observations. (a) Subjects of hyperthyroidism show increased susceptibility to adrenaline administration (Goetsch test). In animals, the

¹ This effect has been made use of to assay the potency of thyroid preparations or to determine the activity of a particular thyroid gland (Gudernatch test).

threshold dose of adrenaline for cardiac acceleration is reduced by a previous administration of thyroid hormone. (b) Thyroxine (p. 681) administration to normal dogs causes hyperglycemia; this does not occur if the adrenal veins have been tied before injection of the thyroid hormone. (c) Marine and Baumann found that injury to the adrenal cortex caused an increase of 60 per cent in heat production. No change in metabolism occurred, however, if the metabolic rate had first been reduced as a result of thyroidectomy. Marine suggests that the adrenal cortex normally exerts, through the pituitary, some inhibitory control over thyroid function.

The following observations suggest an interrelationship between the thyroid and gonads. (a) Thyroid enlargement is frequently observed at puberty and during menstruation or pregnancy. (b) Castration in the dog or rabbit usually leads to a slow reduction in the size of the thyroid and a depression of the metabolic rate (Marine). (c) The continued injection of estrogenic substances into rats or guinea pigs causes thyroid enlargement followed after a few days by involution of the gland. (d) Thyroid feeding is said to inhibit estrus. These thyroid-gonadal relationships are probably brought about through the pituitary.

GOITER

Goiter is a generic term which may be applied to almost any non-inflammatory and non-malignant enlargement of the thyroid gland. The following is a short classification:

- A. *Simple goiters. These are unaccompanied by constitutional features. They are subdivided upon a histological basis into three groups:*
 - (1) Colloid (diffuse)
 - (2) Parenchymatous (diffuse)
 - (3) Adenomatous (nodular)
- B. *Goiters associated with a deficiency of the thyroid hormone (hypothyroidism)*
 - (1) Cretinism
 - (2) Myxedema
- C. *Goiters associated with an excess of the thyroid hormone (hyperthyroidism)*
 - (1) Exophthalmic goiter
 - (2) Toxic adenoma

Diffuse colloid goiter

The alveoli are large, distended with colloid and lined by low cuboidal or flattened epithelial cells. There is no hypertrophy or hyperplasia of the latter (fig. 262 and lower photograph, fig. 266). The iodine content per gram of gland tissue is low but

as a rule the total quantity in the enlarged gland is not far from normal. Colloid goiter may become converted into, or result from, the following type (see also pp. 677-680).

Diffuse parenchymatous goiter

Hypertrophy and multiplication of the cells lining the alveoli, with great reduction in the amount of colloid material are characteristic features of this type. The alveolar cavities are of various sizes and shapes and often almost obliterated by infoldings of their walls. The epithelial cells are high columnar in type. The iodine content of the gland is low, usually much less than 0.1 per cent of its dried substance. Exhaustion of the

FIG. 262. Photomicrograph of a human simple colloid goiter.

gland and atrophy of its secretory elements with an increase in fibrous tissue may result, or, as mentioned above, the goiter may change to the colloid type, especially after iodine administration (fig. 266). Partial thyroidectomy in animals, as first shown by Halsted, results in regeneration of the thyroid remnant to produce the foregoing histological picture of diffuse parenchymatous hypertrophy. This observer also showed that removal of the thyroid from pregnant bitches led to parenchymatous goiter in the puppies.

Adenomatous goiter

As a result of the formation of isolated tumor-like masses of thyroid tissue (adenomata) the glandular enlargement is asymmetrical or nodular. The minute structure of the adenoma may resemble a section of colloid or of parenchymatous goiter, or it may undergo cystic changes. Again, the alveoli may be unusually small, contain little colloid and resemble fetal thyroid tissue (fetal adenoma):

The iodine content of the nodule may be normal or high while that of the rest of the gland, which may also show diffuse colloid or parenchymatous changes, is usually low.

The simple enlargement of the thyroid which sometimes occurs at puberty or during pregnancy may be either of the colloid or parenchymatous type. A certain degree of thyroid enlargement at

FIG. 263. Upper photograph (left), cretinism in an infant; (right), same child after treatment with thyroid extract. (After J. Huxley.) Lower photograph, a cretin aged 10 years. (From McCarrison after Thomson.)

these times is physiological. The enlargements seen in goiter districts (endemic goiter) or occurring sporadically may show the features of any of the three types. Either of the first two forms may end in exhaustion atrophy (p. 677).

HYPOTHYROID STATES

Cretinism

A cretin is a type of dwarf for which deficiency or absence of the thyroid secretion in infancy or early childhood is directly responsible (fig. 263).

Among the typical features of the condition are: (1) retarded and abnormal skeletal growth; (2) arrested sexual development; (3) mental deficiency varying in degree but often amounting to complete idiocy; deaf mutism is common; (4) the facial features are coarse and appear bloated, the skin is dry, thick, pasty and often deeply wrinkled; the nose is broad and its bridge depressed; the tongue is enlarged and appears between the thickened and usually parted lips; (5) the supraclavicular fossae are filled with pads of fat; (6) closure of the anterior fontanelle which normally occurs before the 20th month is postponed for several years; the epiphyses of the long bones fail to ossify at the usual time; (7) the basal metabolic rate is depressed by from 20 to 40 per cent below the normal.

FIG. 264. Left, myxedema. Right, same subject after three months treatment with thyroid extract. (After Murray.)

Endemic cretinism is much less common today. In the past it was seen most frequently in districts where goiter was prevalent—in the valleys of the Alps, Pyrenees, Himalayas, etc.—and was usually the result of atrophy and degeneration of the secretory epithelium of a goitrous gland. Some of the worst cases of cretinism appear, however, in infants, either in these districts or elsewhere, who are not goitrous. The condition is then due to: (a) prenatal or early postnatal atrophy of the thyroid, (b) to its congenital absence, or (c) to its destruction by some inflammatory condition. A large percentage of the goiterless cretins in a goiter district are the result of hypothyroidism in one or both of the parents.

Though the majority of cretins are apathetic and sluggish, some are highly excitable—the *nervous cretinism of McCarrison*.

Myxedema (Gull's disease)

Myxedema is the result of thyroid deficiency in adults or older children and corresponds to the cretinism of infants and younger children. It follows atrophy or destruction of the thyroid from whatever cause, or may result from an operation in which too much of the gland has been removed (*operative myxedema* or *cachexia strumipriva*). The chief characteristics are (a) low metabolic rate (-20 to -40); (b) a thick puffy appearance of the skin; the hair is dry, brittle and sparse; the facial features sometimes give the subject a mongoloid look (fig. 264); (c) apathy, lethargy, slow cerebration, though general intelligence is retained; (d) increased body fat and hypercholesterolemia;

(e) greater susceptibility to cold and (f) cardiac dilatation and low voltage electrocardiograms. The edema-like appearance of the skin was thought by Ord, who suggested the term myxedema, to be due to the accumulation of mucin in the subcutaneous tissues. The thickening of the skin is not due to a true edema, nor is it the result of the accumulation of mucin but, according to Boothby, to the deposit of a semi-fluid albuminous substance containing over 13 per cent of protein, or about the concentration of protein in white of egg. This deposit is looked upon by Boothby and his associates as representing an increase in the normal quantity of stored or deposit protein (p. 546).

A non-myxedematous condition associated with a 20 per cent reduction of the basal metabolic rate, undue susceptibility to fatigue, increased sensitivity to cold and sometimes nutritive abnormali-

ties of the skin, hair and nails is recognized. It is ascribed to a relatively mild grade of hypothyroidism.

HYPERTHYROID STATES

Exophthalmic goiter (Graves' or Basedow's disease)

In Graves' disease there is nothing in the histological appearance of the thyroid to distinguish it, with certainty, from a simple goiter. The gland usually shows a picture typical of parenchymatous goiter, i.e., hypertrophy and hyperplasia (p. 673); its iodine content is low. The blood iodine is elevated. After iodine administration the gland tends to assume the histological appearance of colloid goiter (fig. 266). The blood supply of the gland is greatly increased, the rush of blood through the superior thyroid arteries often producing a loud bruit or a distinct thrill. In addition to the thyroid enlargement the chief features of the fully developed condition are:

(a) Accelerated pulse (100 to 160 per min.) and increased circulation rate (50 per cent or more above normal); cardiac dilatation and hypertrophy; myocardial failure; auricular fibrillation in 20 per cent of cases; flushing of the skin; normal or low diastolic pressure with high systolic pressure (i.e., high pulse pressure).

(b) Nervous excitability.

(c) Muscular weakness and a fine involuntary tremor.

(d) Protrusion of the eyeballs (exophthalmos) and other ocular signs, e.g., widening of the palpebral fissure (Stellwag), as a result of retraction of the upper lid; and infrequent winking; lack of convergence of eyes (Moebius); slow jerky movement of the upper lid or its failure to follow the eye when looking down (von Graefe) (fig. 265).

(e) Metabolic rate increased to varying degrees up to 80 per cent above normal. As a result of the increased activity of the heat-dissipating mechanisms the skin is hot and moist. Increased tolerance to cold and lowered tolerance to a high environmental temperature.

(f) Dissipation of the fat stores; wasting.

(g) Nitrogen and calcium excretion are increased (rarefaction of the skeleton may be demonstrated by X-rays in many cases).

(h) Disturbance of carbohydrate metabolism is common, as evidenced by hyperglycemia, glycosuria and reduced sugar tolerance. Hepatic glycogen stores are reduced.

(i) The thymus is enlarged in 80 per cent of cases.

(j) Subjects of hyperthyroidism are especially susceptible to oxygen deficiency. Work is performed less economically and dyspnea occurs upon exertion (p. 356).

With regard to some of the foregoing features. The tachycardia is not dependent upon nervous connections but appears to be due to a direct and persistent effect of the hormone upon the cardiac musculature. The excised heart of an animal given thyroxine (p. 681) in excess, beats at the increased rate when perfused, or transplanted to the body of another animal. Also, fragments of heart muscle of a two-day-old chick embryo pulsate at a more rapid rate when thyroxine is added to the nutrient fluid. The high pulse pressure seen in hyperthyroidism is due to the general vasodilatation combined with an increased stroke volume. The increased circulation rate is chiefly

FIG. 265. Typical case of exophthalmic goiter showing characteristic facies. (After Crile.)

the result of the higher metabolic rate. The cause of the cardiac hypertrophy and ultimate failure is not altogether clear. In some instances it is probably simply the result of the increased work (greater circulation rate) thrown upon a myocardium already affected by some other disease (hypertension, valvular lesions, etc.). It is also probable that the cardiac condition is dependent upon a specific effect of the thyroid hormone upon the heart muscle. According to Hurxthal the latter is a more potent factor than the increased mechanical work. This observer believes, however, that neither of these factors will induce hypertrophy and failure of a normal heart but that myocardial damage must have pre-existed (see also p. 220). Exophthalmos has been attributed to the contraction of Mueller's muscle situated at the back of the orbit or of the smooth muscle

situated in the fascia bulbi. The contraction of Mueller's muscle was believed, by compressing the orbital contents, to push the eyeball forward. This view was supported by the fact that experimental stimulation or section of the sympathetic in the neck (from which the innervation of this muscle and of the smooth muscle of the fascia bulbi is derived) causes, respectively, protrusion or recession of the eyeball. But, whereas in animals Mueller's muscle is well developed, in man it is a mere vestige and, according to Whitnall, is not concerned in the production of the exophthalmos. Smooth muscle in the fascia bulbi of man, is too small in amount to exert a force which could possibly protrude the eyeball against the restraining action of the ocular muscles (recti). According to Whitnall, the exophthalmos is primarily due to dilatation of the orbital venules and the transudation of fluid into the post-ocular tissues. The absence of lymphatics from this region encourages the accumulation of the transudate; subsequently, organization with hypertrophy of the orbital tissue occurs. Smeltser produced exophthalmos in guinea-pigs by means of daily injections of the thyrotropic hormone of the pituitary and then examined the orbital contents histologically. He found changes closely resembling those observed in the exophthalmos of Graves' disease, namely, edematous and lymphoid infiltrations of the orbital tissues which were increased considerably in bulk. He states that these effects of the thyrotropic hormone can be prevented to some extent by excision of the cervical sympathetic ganglion (which one is not stated). (See also pp. 677, 725.) There appears to be no correlation between exophthalmos and the level of the basal metabolism or any of the other manifestations of hyperthyroidism; indeed, exophthalmos may persist and even progress after thyroidectomy, though the basal metabolism has fallen to normal or below, and other signs of hypothyroidism have supervened. The signs of exophthalmic goiter referable to the eyelids (Stellwag's and von Graefe's) are possibly due to stimulation of the smooth-muscle component of the levator palpebrae superioris (p. 1016) which is innervated by the sympathetic.

Thyroid crises. During the course of exophthalmic goiter intense exacerbation of the symptoms may occur, accompanied by nausea, vomiting, diarrhea, dehydration, high temperature, a great increase in heart rate, erythema, extreme nervousness, thrashing about in bed, muscular weakness, and sometimes delirium or coma. Such a crisis

may occur after operation, and death result from exhaustion or cardiac failure.

Toxic adenoma

A simple adenomatous goiter (p. 673) may undergo increased functional activity and produce the features of pure hyperthyroidism, i.e., those produced by the administration of thyroid extract in excessive amounts, or those described under exophthalmic goiter *minus* the exophthalmos and crises. A simple adenomatous goiter does not give rise to hyperthyroidism until the lapse, on the average, of fifteen years (Plummer). Toxic adenoma occurs at a later age than exophthalmic goiter, which is usually neither preceded by a goitrous condition nor is more prevalent in goitrous districts.² It is said that about 20 per cent of adenomatous goiters eventually become toxic. A toxic adenoma possesses no histological features which distinguish it with certainty from the simple variety.

DISCUSSION OF THE FOREGOING HYPERTHYROID STATES

Many authorities do not draw any physiological or other essential distinction between the two types of hyperthyroidism believing that there is but one disease which differs only in its clinical manifestations. Others find it difficult to believe that certain features of exophthalmic goiter (e.g., exophthalmos, more rapid development, greater nervous excitability, crises and a more favorable reaction to iodine administration) do not indicate a fundamental difference between it and toxic adenoma. Two theories have been advanced in explanation. Plummer, who first separated clinical hyperthyroidism into these two types, believed that in toxic adenoma hyperfunction of the gland alone was evident, whereas in exophthalmic goiter there was dysfunction as well; he suggested that in the latter disease the gland formed not only an excess of the normal hormone, but also one which was abnormal as a result of incomplete saturation of its molecule with iodine (*two-secretion hypothesis*). According to this theory administration of iodine was beneficial presumably because it permitted the formation of a normal secretion. Marine contends, on the other hand, that exophthalmic goiter is not due primarily to thyroid disease, but to a disturbance of some other

² According to Pemberton the last statement applies to Europe, not to America in which the incidence of exophthalmic goiter is higher in goitrous districts.

docrine. The sympatho-adrenal system has been suggested in this connection. Recent work points to involvement of the anterior lobe of the pituitary (p. 680) or the pituitary-hypothalamic mechanism. The underlying disorder whatever it may be, causes stimulation of the gland which in turn is responsible for the raised metabolic rate and other manifestations attributable to the excessive secretion of its hormone. The other features, e.g., the exophthalmos and crises are ascribed to the primary disorder itself. The conception of an extra-thyroid factor is supported by the following observations. (a) The exophthalmic type of thyrotoxicosis is frequently sudden in onset, rapid in development and may appear though there has been no previous thyroid disease. (b) Exophthalmos is rarely, if ever, produced by the administration of thyroid hormone to animals, nor does it occur, except very occasionally, in adenomatous goiter, though signs of hyperthyroidism are clearly evident. Marine and Rosen, on the other hand, have produced exophthalmos in *thyroidectomized* guinea pigs by means of injections of anterior pituitary extracts (see also pp. 681 and 725); and clinically, exophthalmos and nervous manifestations sometimes persist though the thyroid hyperplasia is reduced and the basal metabolic rate returns to normal; the thyrotropic hormone then appears in excessive amounts in the urine. (c) An extract of the gland from subjects of exophthalmic goiter is no more toxic than that of a normal gland, often much less so, when administered to animals or to another victim of the disease. (d) The toxicity of such an extract is proportional to its iodine content. This is the opposite to what one should expect if an iodine-deficient product were responsible for some of the features of the disease. Furthermore, evidence from the chemical side is against the view of a compound poor in iodine being responsible for the toxic symptoms. Diiodothyronine, for example, which is thyroxine less two atoms of iodine, has the same but has an activity only about 4 per cent of the activity of thyroxine itself (p. 681). Thyronine which contains no iodine is inactive. (e) The features of the thyroid crises suggest a profound disturbance of involuntary nervous centers; furthermore, some of the most severe crises are postoperative, i.e., after a large part of the gland has been removed.

THE RÔLE PLAYED BY IODINE IN THYROID FUNCTION

Iodine is an essential element of the thyroid hormone and its administration exerts a profound

effect upon the thyroid tissue. Simple goiter is due to iodine deficiency. This may be (a) an *absolute deficiency* in water and food, (b) a *relative deficiency*, the iodine of the food being sufficient for the elaboration of the amount of hormone required under the ordinary circumstances of life but insufficient under more exacting conditions, e.g., puberty, pregnancy, excessive protein of the diet, etc. (c) It is also possible that certain microorganisms in the intestinal tract may reduce the quantity of iodine absorbed from the food; this would explain McCarrison's observations upon the relationship between the incidence of goiter in India and infected drinking water. It is more likely, however, that infected water, if it does sometimes play a part in the production of goiter, acts in some other way than by merely interfering with the absorption of iodine.

The quantity of iodine in the normal thyroid is about 2 mg. per gram of dried tissue; the average total store in the gland is from 10 to 15 mg. A content below 1 mg. per gram of dry gland according to Marine, is indicative of definite thyroid abnormality; in severe parenchymatous goiter, either simple or exophthalmic, it may be as low as 0.25 mg. or less per gram. In colloid goiters the general level is higher. Marine considers all goitrous enlargements, including the exophthalmic type, as examples of "a compensatory work hypertrophy," brought about by iodine deficiency. The demands made upon the gland to produce its hormone without an adequate iodine supply results in hypertrophy and hyperplasia, or adenomatous growth, and in some instances, final exhaustion and atrophy. This conception is well supported by the following facts: (a) The degree of hyperplasia of the gland is inversely related to its iodine content. When hyperplasia gives place to exhaustion atrophy, the gland is almost iodine-free. (b) A colloid goiter which is an expression of moderate iodine deficiency passes into the hyperplastic type when the iodine intake is further reduced. (c) The parenchymatous hyperplastic picture is converted to the colloid type upon the administration of iodine (fig. 266). Iodine thus induces the storage of colloid (thyroglobulin). The types of simple goiter are looked upon as stages in a process which is responsive to the iodine supplies, the gland sometimes passing several times through a cycle of hypertrophic, hyperplastic and colloid changes; or the cycle may end in atrophy. The successive stages are represented in the following scheme after Marine.

FIG. 266. Upper photograph. Microscopical appearance of the gland in exophthalmic goiter showing hypertrophy and hyperplasia (parenchymatous goiter) before the administration of iodine. Lower photograph, showing appearance after involution had occurred from iodine administration (colloid goiter). (After Rienhoff.)

The thyroid tissue as shown by Marine has a striking affinity for iodine. The gland though constituting only 0.05 per cent or less of the body weight contains about 20 per cent of the body's entire supply of iodine. Marine showed that when the thyroid was perfused with a solution of potassium iodide, relatively large quantities of iodine were taken up by the gland and could not be removed by subsequent washing. This result was not obtained by the perfusion of other organs, e.g., spleen, kidney, etc. The selective action of the intact thyroid for ingested iodine was also demon-

strated. Over 18 per cent of iodine fed to normal animals was recovered from the gland; the fetal gland also stores iodine fed to the mother. According to Salter, the concentration in the blood of the protein bound fraction shows a closer correlation with the symptoms of hyperthyroidism than does the basal metabolic rate.

Blood normally contains from 10 to 12 micrograms (0.010 to 0.012 mg.) per cent. In hyperthyroidism it is nearer 30 micrograms per cent and in hypothyroidism between 7 and 9 micrograms. In health from 25 to 75 micrograms of iodine are

excreted daily in the urine. Most of the blood iodine is in organic form, only a small fraction, probably of dietary origin, being inorganic. The organic portion is bound to protein from which it can be extracted. In the extract are a di-iodotyrosine-like and a thyroxine-like fraction. Knowledge of this subject has been advanced in recent years by the use of radioactive iodine. It has been shown by its aid that the hyperplastic gland has a greater avidity for iodine than has a normal gland, absorbing 80 per cent of a dose (2 mgm.) of iodine within 10 minutes after intravenous injection. A later analysis of the thyroid tissue shows that the free iodine concentration has been quickly reduced and the concentration of thyroxine increased.

Elmer has developed an *iodine tolerance test* based upon the especially high affinity of hyperplastic thyroid tissue for iodine. In performing the test as modified

investigations into the relationship between iodine and goiter; he showed that the iodine content of the soil, water and air of goitrous districts was very low. He attributed the thyroid enlargement to this deficiency, and recommended iodine administration as a preventive. Goiter is not seen along the sea-board. The sea contains an inexhaustible supply of iodine which has been leached from the soil and carried to the ocean in streams and rivers. Sea water contains about 0.02 mg. of iodine per liter, fresh water, as a rule, very much less. The further away from the ocean and the more mountainous the country, the lower is the concentration of iodine in food and water and the higher in consequence is the incidence of goiter.

The following schema modified from Lunde shows the distribution and circulation of iodine in nature:

The circulation of iodine in nature

by Perkin and his colleagues 10 cc. of blood are withdrawn and its iodine content determined; 37 mg. of iodine in the form of Lugol's solution are then given by mouth and the blood iodine determined in samples taken at half-hour intervals during the succeeding two and a half hours. The test, it is claimed, gives valuable aid in the diagnosis of borderline cases of thyroid disease. The curves drawn from the data are considerably higher for normal persons and for those with non-toxic adenomatous goiter, reaching a maximum of around 180 micrograms per cent, than for hyperthyroid subjects (max. 40 micrograms per cent).

Iodine in the prevention and treatment of goiter

Burnt seaweed or sponge, both of which are rich in iodine, have been employed in the treatment of goiter from the days of Hippocrates. Following the discovery of the element in the early part of the nineteenth century, its administration for the cure of many ills, but especially of goiter, became the vogue. As a result of its indiscriminate use its real value was soon lost sight of. Chatin from 1850 to 1860 carried out some of the first scientific

To Marine and his associates is due the credit for establishing the value of iodine in the prevention of goiter. They found that iodine or sea food prevented the thyroid enlargement in brook trout hatcheries. Marine and Kimball carried out experiments upon a large number of school children in Akron, Ohio, where goiter was endemic. They showed that of the group of children given iodine (2 grams sodium iodide in 10 daily doses twice a year) those who developed goiter amounted to only a small fraction of the number of goitrous individuals in a control group in which the iodine intake was not increased above that of the general population. The employment of small amounts of iodine in goiter districts such as Switzerland, New Zealand, Derbyshire in England and in parts of the United States and Canada has proved to be a preventive measure of the utmost value. By the use of this prophylactic, animal breeders in goiter districts have almost entirely eradicated the disease from their live-stock. Once goiter has become established iodine administration is of much

less value but, as already mentioned, a hyperplastic parenchymatous goiter may be converted thereby to the less severe colloid type. Iodine in the form of Lugol's solution³ (10 to 40 minims daily) is invaluable in the treatment of exophthalmic goiter; hyperplasia gives place to the picture of colloid goiter (fig. 266), the symptoms abate, there is a pronounced fall in the basal metabolic rate and the danger of a thyroid crisis is reduced, or, if a crisis has commenced, it may be ameliorated or checked. In the Mayo Clinic, the surgical mortality has been lowered from 3.5 to 0.7 per cent and pre-operative deaths from 2.5 to less than 0.5 per cent since iodine treatment has been instituted. In most cases of toxic adenomatous goiter, iodine is of less value and there is some possibility that it may aggravate the condition.

It is impossible to give an entirely satisfactory explanation of the beneficial action of iodine in exophthalmic goiter. It is not, apparently, that the administered iodine is used for the conversion of an abnormal iodine-deficient hormone to a normal one, as Plummer suggested. Does the iodine act by stimulating the production of colloid which distends the alveoli and thereby blocks the pathways along which the hormone enters the blood stream? This is the view of Marine and is supported by the fact that a pronounced change in the consistency of the gland may frequently be noted immediately following iodine administration; the gland becomes firmer and tender to the touch (iodine thyroiditis) as a result presumably of the distension of the alveoli. Marine believes that when the colloid pressure attains a certain height *absolute* retention ceases, the discharge of the secretion being established at a higher level. This theory offers an explanation for the return of symptoms which frequently follows (in 2 or 3 weeks) the immediate beneficial effects of iodine. The *pressure-retention* conception also seeks to account for the usual failure of iodine to benefit the hyperthyroidism of toxic adenoma; the adenomatous alveoli seldom react by colloid accumulation.

It is probably the increased concentration of iodine in the blood which checks the liberation of the thyroid principle into the circulation and diverts it into the alveoli to be stored as colloid.

Thiourea and *thiouracil* lower the metabolic rate and have come into use in the treatment of thyrotoxicosis. Their action upon thyroid function is unique since in normal animals they cause *thyroid*

hyperplasia together with hypothyroidism. It is Astwood's view that they act by preventing the synthesis of thyroxine by the thyroid. They do not interfere in any way with the action of thyroxine upon the tissue cells because the usual increase in metabolism is observed when either of these drugs is administered with thyroxine. Nor is their effect upon thyroid function due to a relative iodine deficiency for it is not prevented by iodine administration. But these drugs prevent the development of hyperthyroidism which ordinarily results from the injection of thyrotropin and are ineffective in hypophysectomized animals. These observations lead to the conclusion that thiourea and thiouracil have a two-fold action, that they stimulate the production or liberation of thyrotropin by the pituitary which accounts for the thyroid hyperplasia, and also interfere with the production or the liberation of thyroxine. This latter effect explains the hypothyroidism and may be the primary and only direct action of these drugs, the outpouring of the pituitary principle being possibly a secondary or automatic response to the failure of thyroid function.

A consideration of factors other than an absolute iodine deficiency in the development of goiter

The work of McCarrison and others indicates that dietary factors, other than iodine deficiency, are also concerned in the production of goiter. Diets deficient in the fat-soluble vitamins and in vitamin C appear to be conducive to its development. The ingestion of excessive quantities of fat or of protein (especially of liver) also predisposes to it. In rabbits and rats, cabbage has been shown to be powerfully goitrogenic; cauliflower and Brussels sprouts have a similar effect. Iodine deficiency of the diet itself (absolute iodine deficiency) is not a factor in this goitrogenic effect. Drying the cabbage in a vacuum destroys its goitrogenic properties, whereas boiling it with hydrochloric acid does not. A characteristic of these vegetables is their relatively high content of cyanogen compounds. Taking this hint Marine and his associates gave various cyanides to rabbits and obtained a marked thyroid enlargement; methyl cyanide was especially effective. The thyroid hyperplasia was accompanied by exophthalmos.

Marine and his colleagues suggested that the goitrogenic effect of cyanides was dependent upon their property of depressing tissue oxidations, increased thyroid function being a compensatory reaction instituted to oppose this action. It was further suggested that exogenous or endogenous

³ Iodine, 1 gram; potassium iodide, 2 grams; water, 30 cc.

cyanides or defective powers of the body to detoxicate such compounds might be a primary cause of exophthalmic goiter and that the compensatory reaction of the thyroid was brought about through the pituitary or the hypothalamic centers. It is more probable, however, that cyanides (also cyanates and sulphocyanates) exert their effect upon the thyroid either directly or through the pituitary, rather than by depressing tissue metabolism generally, for when a myxedematous patient, in whom the basal metabolic rate was maintained at near the normal level by thyroid administration, was given potassium sulphocyanate daily for six weeks, no reduction in metabolism resulted. This shows that the action of the thyroid principle upon the tissue cells was not impaired. On the other hand, cyanate given to a person with normal thyroid function causes a fall in the basal metabolic rate,—presumably by suppressing the liberation of thyrotropin.

The possibility of infected drinking water, in some instances, playing a rôle in the development of goiter has been mentioned (p. 677). All the factors cited in this section apparently act indirectly, the goitrogenic effect being brought about through the production of a *relative* iodine deficiency, i.e., through the creation of a greater demand for iodine; or, possibly in some instances, through interference with the absorption of iodine. The effects can be counteracted by iodine administration.

THE THYROID HORMONE

A glycerine extract of sheep's thyroids was first employed successfully by the English physician George Murray in 1891 for the relief of myxedema. The thyroid tissue itself when given by mouth was shown subsequently to be physiologically active.

believed that the iodine was present in organic combination and named the compound *iodothyrim*. It was shown subsequently by Oswald (1899) that the active iodine constituent was attached to a protein—*thyroglobulin*—which is the chief component of the colloid material filling the alveoli of the gland.

The active principle of the thyroid was isolated in crystalline form by Kendall in 1919. He named the substance *thyroxin*⁴ and found that it contained 65 per cent of iodine and an amino group. Harington and Barger in 1927 established the chemical formula of thyroxine and effected its synthesis. It was found to be constituted of 2 benzene rings united by an oxygen bridge, and to contain 4 atoms of iodine and an amino-acid side-chain. The synthesis required a number of separate steps.

3:5-di-iodo-4-(4'-methoxyphenoxy) benzaldehyde contains iodine atoms in the same positions as two of those in natural thyroxine—

3:5-di-iodo-4-(4'-methoxyphenoxy) benzaldehyde

This compound having been prepared, the amino group was attached by condensation with hippuric acid. The resulting compound was boiled with NaOH in alcohol and then with acetic anhydride and hydriodic acid. The product of these procedures,—*3:5-di-iodothyronine*—, readily takes up 2 additional atoms of iodine with the formation of thyroxine, when treated with a concentrated solution of iodine in potassium iodide.

Thus—

Baumann in 1896 discovered that iodine was an important constituent of the thyroid extract. By acid hydrolysis of thyroid tissue and later by peptic digestion he obtained a brownish powder containing 10 per cent of iodine and possessing the physiological activity of the whole gland. He

⁴ Now usually spelled thyroxine.

⁶ The numbering of the positions in the thyronine nucleus are shown below.

Synthetic thyroxine possesses physiological properties identical with those of the natural product. Thyroxine is related to tyrosine. Only 40 per cent or so of the iodine in the thyroid is contained in the thyroxine molecule, the remainder is present in di-iodotyrosine:

This compound is formed in the body from tyrosine and almost certainly represents a stage in the synthesis of thyroxine; when added to slices of surviving thyroid tissue di-iodotyrosine is converted to thyroxine. Di-iodotyrosine itself has only slightly physiological activity.

FIG. 267. Effect of thyroxine on a myxedematous patient. (After Harington.)

Before leaving the subject of thyroxine synthesis, two rather astonishing discoveries should be mentioned. A substance identified chemically and physiologically as thyroxine has been obtained by the hydrolysis of iodinated casein with alkali and heat (Ludwig and Mutzenbecher); and the feeding of iodinated serum protein to hypothyroid subjects raises the metabolic rate and relieves the symptoms (Lerman and Salter).

It is very unlikely that thyroxine is identical with the hormone discharged from the thyroid into the blood

stream. Its very low solubility argues against thyroxine being the hormone itself. Moreover, the activity of thyroglobulin (or of the dry gland) is greater than can be accounted for by its free thyroxine content. Thyroglobulin activity is more closely related to total iodine content. A conception which fits the facts best is that di-iodotyrosine and thyroxine are linked together to form a peptide which, combined with other amino-acids, is built up into thyroglobulin (colloid). The disruption of the thyroglobulin by laboratory procedures the highly active peptide is split into the active thyroxine and the inactive di-iodotyrosine. When, on the other hand, thyroglobulin undergoes natural breakdown, the intact peptide which, according to the present conception, is the true hormone, is released into the blood stream.

The action of the thyroid hormone

The thyroid hormone is believed to act as a catalyst to increase the oxidative processes of the tissues or at least to increase the activity of the respiratory enzymes in the cells. The oxygen consumption of tissue excised from a hyperthyroid animal is normal, whereas the metabolism of tissue removed from a hyperthyroid animal is greater than normal. These observations indicate, of course, that the action of the thyroid hormone is exerted directly upon the cells rather than through the nervous system. The effect of a single administration of thyroxine upon the basal metabolic rate is slow to develop and lasts for a long time (fig. 267). It commences after the lapse of about 7 hours, reaches its maximum in from 8 to 10 days and lasts for 6 weeks. Thyroxine brings about the conversion of a relatively enormous quantity of material. 1 mg. causes the total CO₂ output to increase by some 400 grams and elevates the basal metabolic rate by 2.5 per cent. The entire normal adult human body contains about 14 mg. of thyroxine. It has been calculated that the gland maintains this amount constant by manufacturing and delivering about 0.33 mg. per day. In other words, 0.33 mg. of the hormone is consumed daily, and as a matter of fact the daily quantity of administered thyroxine required to maintain the metabolism of a thyroidless adult at the normal level has been found to be about 0.5 mg. Animals when given repeated doses of dried thyroid, or of pure synthetic thyroxine, develop the features of hyperthyroidism, e.g., raised metabolic rate, weight loss, increased excretion of nitrogen and of calcium (chiefly in the feces) reduction of liver glycogen, tachycardia, etc. The coincident administration of amino-acids enhances these effects. The administration of dried thyroid substance by

The form of compressed tablets is a complete substitute for myxedema. Cretinism also, if discovered early, can be immensely improved, and almost normal bodily and mental development secured (figs. 263 and 264). Thyroxine is equally effective. The latter, in that it is a chemically pure substance and so can be accurately measured, possesses an advantage over the dried gland, which is variable in potency.⁶ Nevertheless, thyroxine has the greater disadvantage of being less potent and possessing a less certain action when given by mouth. This is due to its relative instability and its imperfect absorption from the

THE SECRETION OF THE THYROID HORMONE

The thyroid cells under ordinary circumstances discharge their secretion into the alveolar lumen. As, just mentioned, it is stored until required. According to one view, the stored material is then picked up again by the cells of the alveoli and passed into the blood stream. Other investigators believe that the hormone finds its way into the blood vessels via channels between the cells. The first mentioned view is held by Severinghaus who describes the cells as sending pseudopodia-like processes into the colloid which they are believed to absorb and transfer to the blood. When the demand for hormone is great and the reserve store exhausted, the cells may then pass their secretion directly into the circulation.

Though nervous impulses may play some part in regulating the production and liberation of the

A given extract may be assayed either *chemically*, by determining its content in iodine bound in thyroxine according to the method of Harington and Tall or *biologically*. Several biological tests have been used, e.g., the rate of carbon dioxide production in man, the rate of oxygen consumption of rats, or the increased sensitivity of the latter animals to oxygen deficiency, and finally the tadpole test of Gudernatch, in which the rate of metamorphosis is taken as the criterion. The last mentioned test is, however, dependent upon the total iodine content of the specimen (p. 572) and as we know, only a part of this is active in mammals. Axolotls have been used for a similar purpose. Thyroid feeding renders mice less susceptible to poisoning by acetonitrile (Reid Hunt). This fact has also been used as a basis for testing the potency of thyroid preparations.

thyroid hormone, it is now generally accepted that the chief and essential mode of control is by the thyrotropic principle of the anterior lobe of the pituitary (p. 725). Thyroid tissue has been shown by *in vitro* experiments to inactivate the pituitary principle. Reactivation can be brought about by means of heat. The hormone in inactivated form is excreted in the urine of normal persons and of subjects of thyrotoxicosis, and can be detected by heating the urine. In myxedema, active thyrotropin is excreted. It is not improbable that a high concentration of the thyroid hormone in the circulation causes in some way inactivation of the thyrotropic hormone and, thus, an automatic control is exerted over the action of the pituitary principle. There is also evidence that an excess of the thyroid hormone in the blood depresses the output by the pituitary of thyrotropin. On the other hand, thyroglobulin has been found to depress the oxygen consumption of the thyroid which suggests an additional means by which thyroid activity is automatically controlled.

The dispensibility of the thyroid for the synthesis of thyroxine

The surprising discovery has been made that the thyroidless animal can synthesize thyroxine. Morton and his colleagues fed radioactive iodine to rats and recovered radioactive thyroxine later from their bodies. This observation coupled with the fact already mentioned, that iodinated protein possesses thyroxine-like activity, has aroused the speculation that lower forms of animal life, which do not possess a thyroid, utilize as stimulants to metabolism, iodinated protein compounds in their food. If it were possible to obtain a sufficient quantity of such compounds in the diet, higher animals also could probably dispense with the thyroid gland. The thyroid thus is seen as a highly specialized structure which more active forms of life have evolved for the conversion of compounds of low activity formed in the tissues generally, into a principle whose potency has been multiplied a hundred-fold over that of the original material.

CHAPTER LIX

THE ADRENAL GLANDS (SUPRARENAL CAPSULES)

Development and structure

The mammalian adrenal gland, like the pituitary body and the thyroid-parathyroid apparatus, consists of two parts which, though closely associated anatomically, have separate origins, are structurally different and so far as is known, functionally independent. The central part of the gland is called the *medulla*; the outer enveloping rim of tissue is known as the *cortex*. In certain fishes (Elasmobranch) the analogues of these two parts are not joined together. Tissue corresponding to the mammalian medulla, for example, is found as a number of small discrete masses on either side of the spine in association with the sympathetic ganglia, while an elongated structure lying between the kidneys (*inter-renal body*) corresponds to the adrenal cortex of mammals. In the amphibia and reptilia the two types of tissue have come together, but masses of cortical cells are intermingled with islets of medullary tissue and the two tissues are not segregated into a peripheral and a central zone, as in the mammalian adrenal.

The medullary cells exhibit characteristic staining reactions; ferric chloride turns them blue, osmic acid black, and chromic acid or its salts a dark brown. As a result of the last mentioned reaction they are spoken of as chromophil or chromaffin cells.

In all animals the medullary tissue and the sympathetic ganglion cells have a common origin; they develop from primitive cell masses which have separated from the neural crest. Migrating from their sites of origin these masses of ectoderm cells undergo differentiation along two paths, some into sympathetic ganglion cells, others into chromaffin tissue. In the abdomen on either side of the mid-line a relatively large mass of chromaffin cells becomes enveloped by cortical tissue to constitute the adrenal medulla. Other smaller masses persist as accessory chromaffin tissue in association with the ganglia and plexuses¹ of the sympathetic. On the other hand, sympathetic ganglion cells may be found scattered among the cells of the adult adrenal medulla. The cortex is developed from mesoderm. It arises as a bud from the celomic epithelium covering the inner side as the fore part of the mesonephros. The celomic epithelium immediately behind this area gives rise to the germinal epithelium from which in turn the sex glands develop.

The medulla is composed of closely packed groups of polyhedral cells containing chromaffin granules which are looked upon as the mother substance of the medullary secretion. The cell groups are separated by blood sinuses which empty into a central vein. The cells of the cortex are arranged in three zones. These are from without inwards the (1) *zona glomerulosa*, in which

groups of cells are arranged in a circular or oval pattern, (2) *zona fasciculata*, in which the cells are arranged in columns, and (3) *zona reticularis*, which is composed of a network of cell cords (fig. 268). The cells of the cortex contain fine droplets of doubly refracting lipid material which is also seen in the form of dust-like particles in the capillaries of this part of the gland; it probably is the active cortical hormone or its precursor.

The cells of the cortex originate at the periphery of the gland, in the *zona glomerulosa* just beneath the capsule, or more probably from the cells of the capsule itself. These young cells contain numerous mitochondria but relatively little lipid material. As the cells become older they migrate towards the medulla of the gland, the mitochondria become fewer and the lipid material more abundant. The lipid diminishes again later; the migrating cells become shrunken in appearance and finally die near the cortico-medullary junction. The lipid droplets contain cholesterol and insoluble ketones. The mitochondria are believed to be concerned in the production of the cortical hormone. Hypertrophy and hyperactivity of the adrenal cortex (induced by corticotropin p. 726, or by removal of one adrenal) is associated with proliferation of the mitochondria and a decrease in the lipid material. Adrenal atrophy (as follows hypophysectomy) is accompanied by a decrease in mitochondria and the lipid material appears to be increased due to its accumulation into larger droplets clumped together.

On the basis of lipid distribution, the normal adrenal cortex has been divided by Weaver and Nelson into four zones—an *outer zone*, comprising the *zona glomerulosa* and poor in lipid material, a narrow *optically inactive zone*, between the *zona glomerulosa* and the *zona fasciculata*, an *optically active zone* the richest in lipid material its cells being well-filled with fine dust-like particles, and an *inner zone*, relatively poor in lipid and comprising the *zona reticularis* and a small part of the *zona fasciculata*.

Blood and nerve supply

The adrenal is one of the most richly vascular organs in the body, receiving 6 to 7 cc. of blood per gram of tissue per minute. It is supplied by 3 small arteries which are derived, respectively, from the inferior phrenic artery, the renal artery and the aorta. They form rich plexuses in the cortex. The plexuses are continuous with the sinuses of the medulla which drain into the central vein of the latter. The right adrenal vein empties directly into the inferior vena cava. The left vein into the renal vein. The nerves are derived from the great splanchnic, the fibers pass through a plexus (suprarenal) before entering the gland.

¹ Such chromaffin collections are called *paraganglia*.

bers are medullated and have no cell stations in their course. That is, they are entirely preganglionic, the medullary cell itself taking the place of the ganglion cell and postganglionic fiber; they differ thus from all other sympathetic pathways (see p. 948).

THE ADRENAL MEDULLA

Thomas Addison's report in 1855 (p. 697) and the experimental work of Brown-Séquard in 1856 gave the first hints concerning adrenal function. The last-mentioned observer showed that complete removal of the glands from rabbits caused death. The French physiologist Vulpian in the same year discovered that the medulla, unlike any other tissue, was stained blue by ferric chloride, and that the blood of the adrenal vein sometimes gave a

FIG. 268. Section of the human suprarenal capsule. A, medullary portion; B, zona reticularis; C, zona fasciculata; D, capsule; the zona glomerulosa is situated just beneath the capsule. (After Maximow and Bloom.)

similar reaction. The staining reaction, it is now known, is characteristic of the internal secretion of the medulla (adrenaline). In 1894 Oliver and Schafer obtained an extract from the medulla which upon injection caused a pronounced rise in blood pressure. The active principle of the extract was obtained in pure form in 1901 by Takamine and by Aldrich. Upon analysis the latter observer found the empirical formula to be $C_9H_{17}O_2N$. The substance has been given various names—adrenaline, (or adrenalin) epinephrine, adrenin and suprarenin. The first of these names is most commonly used. Adrenaline is closely related to tyrosine, as will be seen from the following structural formula:

Adrenaline is a secondary alcohol, its full chemical name being 3,4-dihydroxy- α -phenyl- β -methylamino-ethanol. It was first prepared synthetically by Stoltz (1904) and later by Dakin (1905). Adrenaline possesses an asymmetric carbon atom, so three isomers are possible (i.e., a levo- and a dextro-rotatory and a racemic form). The natural levo compound is 15 times more powerful than the dextro-rotary. Tyrosine is a probable precursor of adrenaline. The introduction of a second HO group into the tyrosine molecule can be effected by the enzyme tyrosinase present in plants; dioxyphenylalanine (dopa) is formed. Tyrosinase is not found, however, in animal tissues, but it has been shown that dopa can be produced from tyrosine by the action of ultraviolet light in the presence of Fe^{++} ions or ascorbic acid.

THE ACTION OF ADRENALINE

The actions of pituitrin and adrenaline possess certain features in common. They both stimulate the uterine muscle and raise the blood pressure by constricting the vessels. The effects of the two differ, however, in that pituitrin action bears no relation to the sympathetic innervation of the structures acted upon, whereas adrenaline acts only upon structures receiving sympathetic innervation and in a manner corresponding to the action of the sympathetic fibers themselves. In general, its effects imitate almost perfectly those evoked by stimulation of the sympathetic system. Its action therefore is said to be sympatho-mimetic. Adrenaline, for instance, inhibits the muscle of the bowel, pituitrin causes excitation; the latter causes constriction of the coronary vessels, the former dilatation. Yet adrenaline does not act upon the sympathetic nerve endings themselves since its effects are not reduced (indeed they are magnified) by section and degeneration of the nerves (p. 947). It is said to act upon the hypothetical substance in the muscle or gland (*receptive substance of Langley*) in which the nerve fibers terminate.

The effects of adrenaline administration are of shorter duration than those of pituitrin. The pressor effect induced by the former does not persist for more than a minute or two. Adrenaline disappears rapidly after injection, due it is supposed to its oxidation in the tissues. The effects following subcutaneous injection are much less intense, though more prolonged, than those induced by intravenous administration. When given orally adrenaline is inert. Adrenaline is rapidly inactivated in the body. The site of inactivation is mainly in the liver, though the process also occurs in other tissues. Yet outside

the body adrenaline is much more stable in blood and tissue fluids than in Ringer solution, in which it undergoes oxidation to form a red compound. The substances in blood and tissue fluids which have a stabilizing or protective action upon the adrenaline molecule are reducing agents, such as glutathione and ascorbic acid (Welch). It is significant that the adrenal gland is especially rich in these substances.

The actions of adrenaline will be considered under the following headings:

(a) *Circulatory*

In amounts which may be considered within physiological limits (about 0.01 cc. per kilogram of 1 in 10,000 solution administered subcutaneously) adrenaline shows a differential action upon the vessels. The arterioles and capillaries of the skin, mucous membranes and splanchnic viscera (except the intestinal vessels which usually dilate) are constricted; the vessels of the muscles at the same time dilate. With such a dose the constrictor overshadows the dilator effect, the net result being a rise in blood pressure. The coronaries are dilated. Thus, there occurs a redistribution of blood, which is moved from the splanchnic area and skin to the skeletal and cardiac muscles. The vessels of the lungs are little affected, or dilated, by such doses; larger injections cause pulmonary vasoconstriction. The arterioles of the brain are dilated passively by the general rise in blood pressure (p. 292).

It is evident from the foregoing that adrenaline does not, as is often assumed, cause general vasoconstriction. Certain vessels, such as the coronaries, intestine and probably also the vessels of the skeletal muscles, according to Dunlop, are dilated even by relatively large doses of adrenaline. The vessels of the skin and of the splanchnic viscera with the exception of the intestine are constricted by any effective dose.

In very small amounts (0.01 cc. per kilogram of 1 in 50,000 or 1 in 100,000 solution) a fall in blood pressure (*depressor effect*) results. This is attributed to the dilator response in the muscles overbalancing the vasoconstriction in the skin and abdominal organs. A pressor effect, however, may be obtained even with these small doses if the blood pressure is already low or the animal under deep anesthesia. On the other hand, a depressor effect is obtained with large doses if ergotoxine (or ergotamine) an active principle of ergot, has been given previously (fig. 269). Ergotoxine, it is believed, paralyzes the vasoconstrictor

mechanism but leaves the vasodilator intact. It was shown by Hartman and Kilborn in kittens that the vasodilator effect of adrenaline is absent at birth and does not develop fully until the animals are about 11 weeks old.

In animals the *heart* is slowed by adrenaline if the vagi are intact; its beat is strengthened. The slowing is a reflex effect (through sinus and aortic nerves) of the elevated blood pressure, and does not occur if this is kept low by bleeding. Increase

FIG. 269. Lower tracing shows effect of intravenous injection of 0.02 mg. adrenaline upon blood pressure. Upper tracing from the same animal shows the fall in pressure produced by the injection of 0.02 mg. of adrenaline following a previous dose of 0.4 mg. per kilogram of ergotamine tartrate. (After Geiling.)

of both the rate and force of the heart result if the vagi have been cut previously or their effects abolished by atropine. When given subcutaneously (0.5 cc. of the 1:1000 solution) to the human subject, adrenaline quickens the heart rate. Adrenaline greatly increases the oxygen consumption of cardiac muscle.

(b) *Plain muscle*

Adrenaline inhibits the muscle of the stomach, intestine, bronchioles and wall of the urinary bladder.

Both the tone and movements of the intestine² are inhibited (fig. 270); the bronchioles are dilated. It excites the muscle of the gall-bladder, ureter, trigone and sphincter of the bladder, the retractor penis and the pyloric, ileocolic and internal anal sphincters. The uterus, whether pregnant or non-pregnant, is contracted in many animals, but in the cat, rat, mouse, guinea pig and man, the pregnant organ alone is contracted by adrenaline, the non-pregnant is inhibited. As a result of the excitation of the radiating fibers of the iris (dilator pupillae) the pupil is dilated by adrenaline especially if the superior cervical ganglion has been

FIG. 270. Rabbit's intestine in Ringer's solution. At X Ringer's solution + adrenaline 1:100,000,000; at X' Ringer's solution substituted. Time 30 sec. (After Hoskins.)

previously excised. *Mueller's muscle* is stimulated and the eyeball protruded. Retracting of the upper eyelid is caused by the stimulation of its smooth muscle. The *nictitating membrane* of animals is retracted. Adrenaline also stimulates the *erectores pilae muscles* and other smooth muscle fibers in the skin.

(c) Skeletal muscle

Fatigue of skeletal muscle is postponed. The intramuscular injection of adrenaline increases an

² A dilution of adrenaline as high as 1 in 400,000,000 causes inhibition of the intestine. A dilution greater than this causes augmentation (Hoskins).

animal's capacity to perform work. (See fig. 344, p. 826.)

(d) Respiration

After a short initial period of apnea the respirations are increased in rate and depth. The apneic period is apparently secondary to the rise in blood pressure and is brought about through the carotid sinus mechanism (p. 346).

(e) Metabolism

(1) *Carbohydrate metabolism.* Adrenaline administered by injection causes hyperglycemia and glycosuria. It shows an antagonism to insulin—relieving hypoglycemic convulsions. These effects are due to the mobilization of sugar from the liver whose glycogen stores are thus reduced. The hyperglycemic effect is therefore greatest in well-fed animals with an abundant hepatic store of carbohydrate, and of course is not obtained in hepatectomized animals. The glycogen of the muscles is also reduced by adrenaline. On the other hand, there is evidence (Himsworth and Scott) that the rate of removal of glucose from the blood by the tissues is accelerated. When administered to animals after a prolonged fast or in other conditions which deplete the hepatic glycogen stores, adrenaline causes an increase in liver glycogen. The latter is due to the breakdown of muscle glycogen to lactic acid which, diffusing into the blood, is carried to the liver where re-synthesis to glycogen occurs. There is a fall in the inorganic phosphate of the blood due apparently to the phosphorylation of glycogen and the formation of glucose monophosphate. If the adrenaline administration is continued the liver glycogen is converted in turn to glucose which passes into the blood, causing hyperglycemia; it is subsequently reconverted to glycogen in the muscles (Cori). The cycle may be represented in the following scheme:

(2) *General metabolism.* Oxygen consumption is increased by from 20 to 40 per cent, and CO₂ production by from 30 to 50 per cent; the respiratory quotient is therefore raised. In man the increase in the basal metabolic rate occurs within a short time after the subcutaneous injection of

0.5 cc. of a 1:1000 solution; the temperature of the muscles rises. The effect of adrenaline upon heat production has been called by Boothby and Sandiford its *calorigenic* action. The effect is believed by these workers to be partly the result of the hyperglycemia (carbohydrate plethora) and partly to a direct stimulating action upon cellular oxidative processes; it does not occur after removal of the liver (Soskin). The calorigenic effect is not brought about through an action upon the thyroid since it is obtained after thyroidectomy. Moreover the rise in metabolic rate commences within a few minutes and returns to normal within 2 hours or so, whereas the effect of thyroxine upon heat production does not commence for some hours and is prolonged for many days (p. 682). Definite circulatory and respiratory effects accompany the increased heat production. The systolic pressure rises, the diastolic pressure falls. The heart rate and the cardiac output are increased. The respiratory rate and total pulmonary ventilation are raised.

The dose of adrenaline required to produce a detectable metabolic response (rise in blood sugar and in metabolic rate) is considerably less than that which will cause a rise in blood pressure. Also, because of its rapid inactivation in the body, a given dose of adrenaline has a much greater effect upon metabolism if administered continuously over a period than if given in a single injection.

(f) Other effects of adrenaline

(1) Secretion of saliva;¹ (2) lacrymation; (3) sweating in such animals as horses and sheep, but in most other animals and in man the sweat glands, though innervated by the sympathetic, are not excited by adrenaline (see p. 627); (4) contraction of the spleen (stimulation of the smooth muscle of its capsule and trabeculae) and consequent increase in the blood volume and in the red cell count (p. 54); (5) increase in the coagulability of the blood; (6) small doses increase the flow of urine as a result of constriction of efferent glomerular vessels; larger doses constrict both afferent and efferent vessels and through reduction of the renal blood flow diminish the urinary flow (p. 387); (7) a fall, sometimes preceded by a rise, in the potassium of the blood; (8) contraction of melanophores of certain cold-blooded animals, e.g., frog and horned toad (Redfield).²

¹ The contraction of the melanophores of the horned toad which results from adrenal administration occurs when the animal becomes excited. Since in the latter

THE EFFECTS OF CERTAIN SUBSTANCES
ACTION OF ADRENALINE. Ergotoxine or *ergometrine* annuls the excitatory (motor and secretory) of adrenaline or of sympathetic stimulation. Inhibitory effects, e.g., vasodilator, are not interfered with. For this reason certain effects of adrenaline action or of sympathetic stimulation appear unaltered or reversed by *ergometrine*. Thus, as already mentioned, a depressor effect is obtainable with adrenaline if *ergometrine* has been administered previously. After *ergometrine*, adrenaline causes expansion of melanophores of the frog instead of the usual contraction. The hyperglycemic response to adrenaline is abolished after *ergometrine*. A *potentilla* is one which reverses or annuls some of the effects of adrenaline whereas *coumine* enhances its vasoconstrictor, cardiac and pupillary reactions. In their effect on the capillaries, blood pressure and bronchioles, histamine and adrenaline are antagonistic, and adrenal animals show an increased susceptibility to histamine administration. The blood-concentrating effect of histamine administration is lessened or prevented by previous injection of adrenaline. There is no evidence that histamine increases the output of adrenaline from the medulla.

ADRENALINE-LIKE SUBSTANCES. *Ephedrine* isolated by Chen in 1924 from the Chinese plant *Ephedra*. Its chemical resemblance to adrenaline makes it from the formula:

Ephedrine 1-phenyl-3-methylamino propan-2-ol

This alkaloid is closely similar to adrenaline in its action, causing bronchial relaxation, vasoconstriction, hyperglycemia, inhibition of intestinal peristalsis, excitation of other smooth muscle. It has a calorigenic action, its pressor effect (Cushing) is annulled by *ergometrine* and reduced by *coumine*. It is about 1000 times less powerful than adrenaline and its effects are more prolonged. Because of its pressor effect it is often combined with adrenaline in commercial preparations. Unlike adrenaline it is not taken by mouth, 50 to 150 mg. has produced rise in blood pressure. Tyrosine is formed by the action of bacteria on *tyrosine* (decarboxylation of tyrosine). It is also in the salivary glands of certain molluscs. It is called an *adrenalin* and resembles in some of its actions, e.g., it elevates the blood pressure and stimulates the uterine muscle. Its formula is:

instance the effect is abolished if the adrenal medulla is removed but not when the adrenal glands are not, the effect must be due to a rise in the blood pressure—presumably adrenaline—in the blood.

ine (4-hydroxy- α -phenyl- β -amino ethane)

is another substance closely allied chemically to adrenaline, as shown in the following formula:

phenedrine (α -phenyl- β -amino propane)

This compound has a stimulating action upon the nervous processes somewhat like that of caffeine, inducing alertness, postponing mental fatigue and relieving nervous depression.

Some skins of certain toads secrete substances (*bufotoxins* and *bufoteninedine*) similar in action to adrenaline; the secretion of these substances is increased during excitement.

EMPLOYMENT OF ADRENALINE IN MEDICINE.

Adrenaline is used: (a) to staunch bleeding from accessible surfaces (epistaxis, hematemesis) or from

On account of its pressor effect it is of no value and may do harm in pulmonary hemorrhage and in cases of internal bleeding. (b) To shrink mucous membranes, especially of the nose, and is then frequently in combination with ephedrine. (c) To relax the muscles of the bronchioles in asthma; the relief following its use is very striking. (d) To combat certain allergic reactions, e.g., serum sickness, and to antagonize the action of the histamine-like substances supposedly present in the skin in such conditions as urticaria and angioedema. (e) To stimulate the respirations or to restart the heart which has ceased to beat; in the latter event it may be given by injection into the cardiac muscle. Adrenaline is of value in syncope due to Adams disease (p. 192). It should be mentioned that the administration of adrenaline during general anesthesia is attended by the danger of inducing ventricular fibrillation (p. 198). (f) To enhance and prolong the action of cocaine and similar anesthetics; the vasoconstriction thus induced retards the absorption of these substances, thus prolonging their effects and reducing their toxicity. It is also used as an aid in spinal anesthesia.

BIOLOGICAL TESTS FOR ADRENALINE

Intestinal segment. The fluid suspected of containing adrenaline (blood, serum, etc.) is applied to a segment of surviving rabbit intestine. Inhibition of the peristaltic movements will result if the fluid contains adrenaline. An estimation of the adrenaline concentration in the fluid may be arrived at by matching its effect with that of an adrenaline solution of known concentration.

Segment of the non-pregnant uterus of the rabbit. Employed in a similar manner. This test is also used in the presence of adrenaline.

(c) *Isolated arterial rings.* A ring of a small artery known to react to adrenaline by constriction is suspended in Locke's solution. The arterial ring is attached by a thread to a lever applied to a smoked surface. The fluid to be tested is added to the bath in which the arterial ring is immersed.

(d) *The denervated iris.* Removal of the superior cervical ganglion renders the pupil highly sensitive to the dilator action of adrenaline (the paradoxical pupillary reaction of Meltzer). The fluid to be tested is instilled into the conjunctival sac of an animal so prepared.

(e) *The caval pocket method of Stewart and Rogoff.* This is an auto-assay method. The liberation of adrenaline is demonstrated through its action upon the denervated iris. The inferior vena cava is clamped below the entrance of the adrenal veins and again just below the diaphragm. All veins entering this caval pocket, except the adrenal veins, are ligated. After a measured period of time the upper clamp is removed; dilatation of the pupil results if adrenaline has been secreted in the interval between the closure and opening of the upper clamp. In quantitative determinations the lower clamp is removed and the blood collected through a cannula inserted into the vein. The concentration of adrenaline in the collected blood is then estimated from tests upon a segment of beating intestine.

The denervated heart (described on p. 690).

THE SECRETION OF ADRENALINE

The secretion of adrenaline is under nervous control. Whether or not adrenaline is discharged continuously into the blood stream under ordinary circumstances is a debatable question. Stewart and Rogoff estimated that in anesthetized animals the glands discharged 0.0002 mg. of adrenaline per kilogram of body weight per minute. But, since anesthesia and operative procedures stimulate the adrenal medulla, such experiments do not settle the question of a spontaneous liberation of adrenaline under normal conditions. During rest and under physiological conditions the concentration of adrenaline in the blood is probably not greater than from 1:2,000,000,000 to 1:1,000,000,000 (Rogoff). Such a high dilution has no demonstrable effect in the intact normal animal. On the other hand, Cannon and Rapport found that in states of stress (see emergency function, below) or during splanchnic stimulation, the output of adrenaline amounted to from 0.003 to 0.004 mg. per kilogram per minute. Reduction or exhaustion of the adrenaline content of the gland results from stimulation of the great splanchnic nerve, puncture of the floor of the fourth ventricle or reflexly from excitation of a sensory nerve. The adrenaline

liberation caused by one or other of these procedures may cause an increase in metabolism of over 20 per cent. Anesthesia, asphyxia, strenuous exercise, etc., or the administration of such drugs as strychnine, nicotine and morphine also cause the secretion of adrenaline if the nerves to the glands are intact, but not after the gland has been completely denervated. Massage of the adrenal also causes the passage of adrenaline into the blood stream. Cannon and Rapport place the center for the control of adrenal secretion in the upper part of the floor of the fourth ventricle. This is probably not the highest center since stimulation of the hypothalamus will cause a discharge of adrenaline. The concentration of adrenaline in the resting gland is about 0.1 per cent of its moist weight and the total store in both adrenals of man is about 10 mg. High temperature and infections are said to cause a reduction of the adrenaline store.

THE RÔLE OF THE ADRENAL MEDULLA IN THE BODY

That the effects of adrenaline when administered by injection represent the physiological actions of the medullary secretion in the living body are strongly suggested by the following facts: (a) The almost perfect correspondence between the effects of adrenaline administration and those resulting from the stimulation of different nerves of the sympathetic system; (b) the common origin of the adrenal medulla and the sympathetic nervous system; (c) the discharge of adrenaline into the blood stream under the experimental conditions mentioned above and the researches to be immediately described.

The adrenal medulla is not essential to life. In animals one adrenal may be removed completely and the medulla of the other excised without any apparent ill effect—the animal survives the operation indefinitely.

The emergency theory of adrenal function

Cannon and his colleagues have furnished convincing evidence that the medulla liberates its secretion in significant amounts only under conditions which call for unusual effort on the part of the body to perform work, to prevent changes in its internal environment or to resist threatened dangers. In such times of stress the medullary secretion, it is believed, reinforces the sympathetic nervous system. Through this hormonal-nervous cooperation the several bodily reactions associated with such states of emergency are raised to maximal efficiency. Cannon and his

associates employed the denervated heart as an indicator of adrenaline liberation. The operation for denervation comprises section of the vagi and removal of the stellate and second thoracic ganglia of the sympathetic chain; the heart is thus completely isolated from nervous control. Since in their experiments any effect due to a change in the temperature of the blood was excluded, a pronounced acceleration of a heart so prepared was taken to be the result of a chemical substance carried in the blood stream. Fright, rage, pain, asphyxia, anesthesia, metabolites resulting from muscular activity, exposure to cold, stimulation of a sensory nerve and several other conditions, caused within 10 seconds an increase in heart rate of from 20 to 40 beats per minute. Removal of the adrenals, their denervation, or ligation of the adrenal veins, prevented this effect. The conclusion, therefore, is justified that the various conditions mentioned cause the reflex liberation of the medullary hormone. The denervated heart responds to as little as 1 part of adrenaline in 1400 million parts of blood. In some of Cannon's experiments, cats were frightened by the barking of a dog; the rate of the denervated heart increased by from 15 to 30 beats per minute. The cardiac acceleration was accompanied by pupillary dilation, erection of the hairs and spitting. When motor activity, e.g., struggling in the animal holder, accompanied the emotional excitement the cardiac acceleration was more pronounced (40 to 80 beats per minute). Even minor muscular movements without emotion, e.g., extending the legs, walking or turning the body caused an acceleration of from 5 to 20 beats.

The hyperglycemia and glycosuria resulting from emotional excitement in man and animals is probably associated with the discharge of adrenaline, since it has been shown that the continuous rise in blood sugar which occurs during the emotional reactions (sham rage) following removal of the cerebral cortex (p. 884), is dependent upon the adrenals. The blood sugar continues to rise after this operation, though the glycogen stores of the liver are removed from nervous control by sectioning the hepatic nerves. On the other hand, the effect does not occur after removal of the adrenals, even though the hepatic nerves are intact. In those instances in which the emotional state does not follow the operation of decortication, the hyperglycemic effect also fails to appear. Puncture of the floor of the fourth ventricle and stimulation of the adrenal nerves also cause

hyperglycemia though the hepatic nerves have been previously cut.

Though direct evidence is difficult to obtain it is reasonable to assume that besides the effects mentioned above, adrenaline when secreted into the blood stream brings about other actions which we have seen to be characteristic of its action when injected.

A recapitulation of the actions of the sympatho-adrenal system will show how important these several actions are in fitting an animal for defense or flight; for attack or pursuit. (1) The rise in general blood pressure accompanied by dilatation of the vessels of the contracting skeletal muscles, and of the coronary arteries; and the increased force and output of the heart, raise the circulatory system to a state of maximal efficiency. (2) Hyperglycemia indicates the mobilization of the carbohydrate stores of the liver: thus an adequate supply of fuel for the active muscles is ensured; muscular fatigue occurs less readily. (3) Increased oxygen capacity of the blood is brought about by the discharge of red cells from the spleen. (4) Bronchiolar dilatation and an increase in the rate and depth of respiration permit an increased oxygen intake to supply the tissue cells; at the same time the level of oxygen consumption of the latter is raised. (5) Shortened coagulation time of the blood lessens the danger from hemorrhage. (6) Finally, the emotional manifestations of man and the fighting attitudes or defense reactions of various animals are sympatho-adrenal effects, e.g., pupillary dilatation; protrusion of the eyeballs; cutaneous vasoconstriction; acceleration of the heart; contraction of smooth muscle in the skin causing "gooseflesh" in man, and the erection of the hairs, quills or feathers of animals; sweating; salivary secretion (cat),⁴ and the color changes of some cold-blooded animals

The tonus theory of adrenal function

It has been thought in the past that the medullo-adrenal secretion maintained the sympathetic nerve endings in a state of sensitivity or tone and that the height of the normal blood pressure was dependent upon the continuous discharge of the hormone into the blood. Low blood pressure has been ascribed to adrenaline deficiency (so-called hypoadrenalemia) and essential

⁴ It is an interesting and perhaps a significant fact that in the cat in which spitting is a defense reaction sympathetic stimulation causes a profuse watery flow of juice from the salivary glands. In other animals sympathetic stimulation causes a scanty flow of viscid saliva, a watery secretion being caused by parasympathetic excitation.

hypertension to the liberation of adrenaline in excess (hyperadrenalemia). Nevertheless, the experimental evidence against such conjectures is conclusive. In the first place, if one adrenal be excised and the medulla of the other burnt or curetted away, no fall in blood pressure occurs, so long as a portion of the cortex remains. Furthermore, even if any significant quantity of the hormone were in circulation under ordinary resting conditions its concentration would be within the range which would cause a depressor rather than a pressor effect (p. 686). That a continuous pressor effect is not exerted by circulating adrenaline was shown by Hoskins. He injected small quantities of adrenaline into the blood stream of a quiet animal. A fall in pressure resulted, whereas, if the effect of the injected dose had become added to a pressor effect of adrenaline already present in the blood stream it is obvious that a rise in blood pressure should have occurred. Not until the injected dose was considerably increased did any pressor effect appear. To cite other observations against the view that essential hypertension is due to overactivity of the adrenal medulla, the blood of subjects of this condition does not contain an appreciable amount of adrenaline and the glands of such persons do not contain an adrenaline store greater than normal.

There are certain types of vascular hypertension, however, which are most probably, or certainly, of adrenal origin. The high blood pressure of pituitary basophilism, for example (p. 737), is probably the result of adrenal stimulation. Adenoma of the adrenal medulla itself or of outlying chromaffin tissue (phaeochromocytomata) is certainly the cause of hypertension in some instances. The hypertension is paroxysmal in character, due apparently to the periodical discharge of adrenaline into the blood stream; it is not uncommonly accompanied by hyperglycemia.

DENERVATION OF THE ADRENALS IN THE HUMAN SUBJECT

This operation has been performed with the object of influencing the course of certain diseases, e.g., diabetes, exophthalmic goiter, in which hypersecretion of the adrenal medulla has been supposed to play a part in their causation. It cannot be stated too emphatically, however, that attempts to modify adrenal function in this manner are never justified. Rogoff has reported a case of Addison's disease (p. 697) which apparently was the direct result of denervation of the adrenals in a diabetic subject.

SYMPATHIN

It has been mentioned that the *prompt* acceleration of the denervated heart does not occur in adrenalectomized animals during excitement, sensory nerve stimulation, etc. Cannon and his colleagues find, however, that a *slowly developed* acceleration of the denervated heart occurs during

excitement or muscular activity though the adrenals have been extirpated. The increase in heart rate takes about a minute to develop, reaches its maximum in about 3 minutes and then gradually subsides. Its occurrence is not prevented by the removal of all accessory adrenal tissue, by hypophysectomy or by the excision of the thyroid, parathyroids or gonads, or by denervation of the liver. It is abolished, however, by removal of the sympathetic chains. It was also found that the characteristic slow acceleration of the heart occurred when the lower abdominal sympathetic chain was stimulated. The latter nerve contains fibers supplying the smooth muscle of the skin which are responsible for the erection of the tail hairs. Secretion of the denervated salivary glands, contraction of the nictitating membrane, a rise in blood pressure and of blood sugar also resulted from the stimulation of the abdominal sympathetic. These effects as well as the cardiac acceleration occurred though the cord had been divided in the thoracic region, and the sympathetic chain above this level removed. A material originating in the hind part of the animal was evidently conveyed in the blood stream to the heart and other structures mentioned. Blocking the blood flow returning from the area supplied by the stimulated nerve or removal of the patch of skin prevented the cardiac response. As a result of these researches Cannon and his associates conclude that during sympathetic stimulation a chemical substance resembling adrenaline in its action is liberated from the sympathetic endings supplying the smooth muscle of the skin. They have named this substance *sympathin*. Evidence has also been procured for the liberation of sympathin from other sympathetic nerves, e.g., those of the gastrointestinal tract, cardioaccelerators, hepatic nerves, hypogastric, cervical sympathetic, etc.

Sympathin though resembling adrenaline is not, according to Cannon and Rosenblueth, identical with it. Adrenaline, as we have seen, causes both excitatory and inhibitory effects, whereas evidence is presented for the existence of two kinds of sympathin, one purely excitatory, the other purely inhibitory. The former, called *sympathin E*, is liberated within structures excited by sympathetic impulses, e.g., cardiac muscle, liver, vessels and smooth muscle of the skin, etc. The other sympathin, called *sympathin I*, is liberated in structures inhibited by sympathetic impulses, e.g., intestinal wall, coronary vessels, etc.

Though in many ways sympathin and adrenaline resemble one another, e.g., the actions of both augmented by cocaine and both give the Viale reaction, Cannon and Rosenblueth base their view that the two agents are not identical upon certain similarities. For example, adrenaline causes both excitatory and inhibitory effects which cannot be separated, whereas a sympathin with an excitatory action alone can be demonstrated. When a branch of the splanchnic nerve sending fibers to both the cecum and the liver is stimulated, the sympathin produced (by excitatory impulses to blood vessels of the liver, and inhibitory impulses to intestine) contracts the nictitating membrane and relaxes the non-pregnant uterus; but if the nerve fibers to the liver are stimulated alone the sympathin which is released causes contraction of the nictitating membrane but does not inhibit the uterus. The converse experiment, namely, stimulation of nerves with a purely inhibitory action, cannot be performed, for such do not exist, since some constrictor (excitatory) fibers to blood vessels are always present. Another distinction between adrenaline and sympathin is afforded by the action of ergotoxin. Adrenaline administration following treatment with ergotoxine causes a fall in blood pressure, whereas sympathin liberated by the stimulation of the hepatic nerves causes a rise.

THE ADRENAL CORTEX

FUNCTIONS

The cortex of the adrenal, unlike the medulla, is essential to life. Removal of more than about five-sixths of this part of the adrenal causes death within a few days. Removal of the intermediate body of Elasmobranch fishes (p. 684) is also fatal. Stewart and Rogoff found that the average survival time of dogs after complete double adrenalectomy was 10 days and the maximal time 15 days. They observed that pregnant animals, those in heat (pseudopregnancy) actually survived much longer. For this reason, they suggested that some substance formed at these times substituted for the cortical hormone. This observation has been amply confirmed, and it has been shown further that the survival of adrenalectomized dogs and rats is extended by the administration of progesterone (p. 752). Stewart and Rogoff showed also that the lives of completely adrenalectomized animals could be prolonged by the injection of a cortical extract combined with transfusion of saline. Hartman too obtained a cortical extract which he called *cortin*. This was capable of definitely prolonging the survival time of adrenalectomized animals. Swingle and Pitts

1930 extracted by means of lipid solvents a very potent substance from the cortex which counteracted the effects of adrenal deprivation. When treated with this preparation adrenalectomized animals survived indefinitely; it also proved highly successful in the treatment of Addison's disease.⁵

A brief outline of the chemistry of adreno-cortical principles. Some twenty crystalline steroid compounds have been isolated from the adrenal cortex which exhibit in greater or less degree the physiological properties of crude cortical extracts. The formulae of four of these, namely, *desoxycorticosterone*, *corticosterone*, *11-dehydrocorticosterone* (Kendall's compound A) and *11-dehydro-17-hydroxycorticosterone* (Kendall's compound "E" and Reichstein's compound "Fa6") are given below.

This synthetic compound, which exerts its action predominantly upon water and salt (Na and K) metabolism, is administered in the form of the acetate either subcutaneously or intramuscularly in oil, or in the form of pellets implanted beneath the skin. A material called the *amorphous fraction* remains after the removal of these crystalline compounds from the crude extract. The several physiological actions obtained with a crude extract are not all exhibited, at least fully, by any one of these compounds. Thus, *desoxycorticosterone* has little or no effect upon carbohydrate metabolism, whereas *corticosterone* which shows this effect to a marked degree exerts a minor action upon the metabolism of water and salt (see also p. 695). Besides these compounds, with actions specific for the adrenal cortex, steroids

Corticosterone was isolated by Reichstein and his associates in 1937. Desoxycorticosterone, which has one less oxygen atom, was synthesized later by Steiger and Reichstein from stigmasterol.

⁵ Dogs are employed in assaying the potency of the extract. A dog unit (D.U.) is defined as the minimal daily quantity per kilo of body weight which will maintain for from 7-10 days an adrenalectomized dog in normal condition, as judged by the blood, non-protein nitrogen level and body weight.

with actions of estrone, progesterone and the male hormone, respectively, have been isolated from the adrenal cortex. The last mentioned principle has been named *adrenosterone*.

The manifestations of cortical deficiency in animals

An animal which has been completely adrenalectomized shows the following features during the short period of its survival. Loss of appetite,

(particularly for fats), vomiting, diarrhea, rapid loss of weight, weakness and prostration; fall in body temperature by several degrees; hypotension; and a reduction of 20 per cent or so in the basal metabolic rate (fig. 271). The stimulus of a cold environment upon heat production is much less than in normal animals. The blood becomes concentrated (loss of plasma water) and shows a fall in sodium and sugar, and a rise in non-protein nitrogen, phosphate, calcium and especially of potassium. There are, reduced excretion of urinary nitrogen and other signs of renal failure. Anemia may occur.⁶ The glycogen stores of the liver and muscles are reduced. These changes, as well as the effect upon the electrolyte concentrations of the blood, are detectable within 42 hours

FIG. 271. Characteristic changes in metabolism, circulation and blood concentration in a group of adrenalectomized animals following withdrawal of extract. (After Loeb.)

following adrenalectomy. Post-mortem examination frequently shows congestion of the gastrointestinal tract and pancreas.

The foregoing picture can be entirely prevented by the administration of an extract of the cortex and even comatose animals can be restored to health; heat, pregnancy and lactation proceed normally in adrenalectomized bitches, and growth is maintained in adrenalectomized puppies.

The cortex quite evidently is concerned in some way with mineral and water metabolism. In adrenalectomized animals as well as in the adrenal

⁶ Pigmentation as seen in man has not been observed in lower animals, though, according to Hartman in white cats a grayish discoloration of the skin may be noted. Bronze freckles have also been described in adrenalectomized monkeys and pigmented spots in the buccal mucosa of dogs.

insufficiency of man, a marked reduction in total base occurs which is due entirely to the loss of sodium. The potassium concentration of the serum is raised above the normal level, the rise being due to reduced excretion by the kidney as well as to leakage from the tissue cells into the extracellular fluids. The loss of sodium is accompanied by an increased elimination of water. Marked dehydration results. The administration of sodium chloride to adrenalectomized animals and a reduction in the potassium intake exert a definitely beneficial effect. On the other hand the withdrawal of salt from the diet increases the severity of the condition. The sodium rather than the chloride ion is the important factor.

The reduction of blood sodium was observed originally by Bauman and Kurland, and the beneficial effects of transfusions of saline in sustaining adrenalectomized animals were described by Stewart and Rogoff and by Hartman, but the importance of sodium loss in the development of the symptoms was first pointed out by Loeb and his associates and by Harrop. The value of a low potassium content of the diet in the survival of adrenalectomized animals was shown by Allen and his associates. Completely adrenalectomized animals can be maintained in good health without cortin if placed upon a diet low in potassium but high in sodium chloride and, in order to prevent the acidosis which otherwise develops, containing sodium citrate. The tendency to hypoglycemia is controlled by a high carbohydrate diet. These measures, however, do not completely restore the animal to a physiological state, for they are unable to withstand stress or to perform work with full efficiency.

It is claimed that increased susceptibility to certain toxic agents, e.g., histamine, morphine, diphtheria toxin, etc., is another manifestation of adrenal insufficiency. The adrenal cortex also appears to be concerned in some way with the maintenance of the nutrition of certain nervous tissues; degenerative changes have been noticed in autonomic ganglia (cervical, stellate and celiac) following adrenalectomy, and almost complete loss of function of the vasomotor and cardiac accelerator nerves in adrenalectomized animals was demonstrated years ago by Elliott and more recently by Clegburn and associates. The intestinal absorption of water and electrolytes and the diuretic response to water drinking are greatly reduced in adrenalectomized animals. The relationship of the adrenal cortex to the development of renal hypertension is described on page 132 and its use in burn shock on page 767. The rôle of the cortex in lactation is discussed on page 767.

The physiological actions of the cortical extract and of its different fractions

The general description just given of the actions of the relatively crude extract of the adrenal cortex (cortin) in restoring the health of adrenalectomized animals may now be supplemented by an account of certain other effects which result from the administration of adrenocortical fractions. Cortin, as shown by Britton and his associates, raises the blood sugar and increases the liver glycogen in normal as well as in adrenalectomized animals. The effect upon carbohydrate metabolism is exhibited by those compounds with an oxygen atom at carbon 11, especially corticosterone. Their fundamental action is upon the conversion of protein to glucose (gluconeogenesis), the hyperglycemic effect being accompanied by an increase in the glycogen stores. These compounds thus exert a glycotropic or anti-insulin action and are capable of preventing insulin convulsions. Nothing further need be said here concerning the rôle played by the adrenal cortex in carbohydrate metabolism, since this has been dealt with in Chapter L. The effect of cortin upon the electrolyte concentrations in the body fluids is not confined to adrenalectomized animals, for Thorn and his associates have shown that it reduces the urinary excretion of sodium and increases that of potassium in healthy persons and in normal dogs. Cortin postpones muscular fatigue, a normal animal being capable of greater work under its influence. This action is exhibited to the greatest degree by corticosterone and other compounds possessing an oxygen atom at C_{11} ; desoxycorticosterone is inert in this respect. Corticosterone, dehydrocorticosterone and compound E exert a minimal effect upon water and salt metabolism. The restoration of normal kidney function is exhibited by desoxycorticosterone but to the greatest degree by the amorphous fraction. Either of these compounds causes a prompt reduction in the non-protein nitrogen of the blood. The most outstanding action of desoxycorticosterone is upon salt and water metabolism; it increases the plasma volume and the concentration of sodium in the body fluids, but reduces that of potassium. These effects are due largely but not entirely to an action upon the renal tubules (p. 385). They are partly extrarenal for this steroid appears to influence membrane permeability of the tissues generally; the intracellular potassium concentration is increased and the sodium concentration reduced. As a

result of its effect in causing the retention of sodium and water, desoxycorticosterone administration may be followed by edema. In large doses it may cause more serious effects, e.g., hypertension, dilatation of the right ventricle and pulmonary congestion. Death from cardiac failure has resulted from its clinical use. The manner in which desoxycorticosterone induces these ill-effects is not altogether clear. The rapid increase in plasma volume, and, as a result of this, the extra burden thrown upon the cardiovascular system is suspected of being an important factor. Depression of the potassium concentration of the body fluids may be the lethal factor in some instances; Loeb and his associates have shown that the administration of desoxycorticosterone to animals may lower the potassium level to the point where paralysis results. The administration of potassium salts or a reduction in the sodium intake is undoubtedly of benefit in patients receiving large doses of desoxycorticosterone.

An influence upon growth has been demonstrated (by Hartman and Thorn) for desoxycorticosterone and the amorphous fraction. Young adrenalectomized animals show retarded growth which is resumed when either of these preparations is administered. Corticosterone and compound E, on the contrary, actually inhibit growth.

The reputed action of cortical principles in reducing capillary permeability should be mentioned, since such an effect affords a theoretical basis for their use in surgical and burn shock. Menkin has reported that the dilatation and increased permeability of the capillary vessels caused by inflammatory exudates (see p. 75) can be reduced or prevented by the administration of extracts of the adrenal cortex.

The table on page 696, summarizes the principle physiological actions of the different fractions of the adrenal cortex.

The adrenal cortex and the sex functions. Several observations point to the cortex as being in some way associated functionally with the gonads; among these observations are (a) animals during heat or pregnancy withstand adrenalectomy better than at other times, and progesterone lengthens the life-span of adrenalectomized rats; desoxycorticosterone, on the other hand, exhibits progesterone activity. Estrogens and androgens can be extracted from the adrenal cortex and are found in normal urine. The excretion of these substances also occurs in eunuchs and in ovariectomized women, which indicates that they are

Amorphous fraction	<div><div>(a) Most effective in restoring renal function</div><div>(b) Nearly as potent as desoxycorticosterone in maintaining life in adrenalectomized animals</div></div>

Certain other effects of cortical principles, some of which have been referred to elsewhere, may be mentioned very briefly. The administration to normal rats of corticosterone and of other compounds with an oxygen atom at C₁₁ causes atrophy of the adrenal and thymus within a week or ten days. Progesterone activity of desoxycorticosterone has been demonstrated. As already stated (p. 694) sensitivity to certain toxic agents is increased by adrenalectomy; adrenalectomized animals are also less resistant to cold. Cortical extracts correct these defects. Corticosterone, compound E and the amorphous fraction are about equally effective in protecting against low temperatures; desoxycorticosterone is less active. The parenteral administration of the latter compound, especially if combined with the administration of sodium chloride, is effective against the action of histamine and has been reported to be of benefit in the treatment of severe infections. Hartman and his associates have secured evidence of a relationship between cortin and vitamin C. Cortical extracts relatively free from vitamin C are capable, it is stated, of partially protecting animals from vitamin C deficiency.

derived, in part at least, from the adrenal cortex. It is not improbable that normally the adrenal

cortex, through the manufacture and liberation of these hormones plays a rôle in the control of the sex functions. The persistence of the sex libido after the excision of the gonads (p. 744) conform with such an idea. (b) corticosterone and the sex hormones are closely related in chemical structure (c) the cortex enlarges during pregnancy, and special cells (cells of Stilling) appear in the adrenal cortex of the frog during the mating season; (d) the ovaries of hypophysectomized tadpoles are enlarged by injections of cortical extract; (e) in women the intermenstrual periods are said to be shortened by from 3 to 5 days by the administration of cortical extract (Hartman and associates) (f) cortical extracts have been reported to cause precocious sexual maturity in rats; (g) sexual abnormalities are striking features associated with tumors of cortical tissue (p. 698); (h) the origin of the genital organs and cortex from a common embryonic tissue (celomic epithelium).

The immediate cause of death in cortical deficiency has been a much debated question. Concentration of the blood due to the loss of blood fluid through abnormally permeable capillaries is a prominent feature in animals dying of adrenal insufficiency. Swingle and Pfiffner believe that this increased capillary permeability is an important if not the primary factor in causing death and suggest that the hormone in some way maintains normal capillary permeability and a balanced interchange of fluid between the tissue and the vessels. A normal animal reacts to hemorrhage by dilution of the blood and a rapid restoration of the blood volume. In the adrenalectomized animal, on the other hand, hemorrhage fails to cause blood dilution. These workers draw attention to the similarity of the manifestations of adrenal insufficiency and surgical shock (p. 258). Others stress the disturbance in mineral metabolism as the basic lethal factor and state that most of the effects of adrenalectomy can be induced by the intravenous injection of potassium salt. Britton and his associates have shown, however, that adrenalectomy in the opossum does not cause a loss of sodium chloride, which throws some doubt upon this explanation, for if the loss of sodium chloride were of fundamental importance one would not expect a species difference. Furthermore, some subjects of Addison's disease die although the electrolytes of the blood have been restored to normal. In certain instances hyperglycemia is the immediate cause of death.

DISEASE OF THE ADRENAL CORTEX IN MAN

Addison's disease

The syndrome known today as Addison's disease was first described (in 1855) by Thomas Addison and ascribed by him to tuberculous disease of the adrenals. Experimental and clinical observations since that time have fully substantiated Addison's conclusion that the disease is due to adrenal involvement. Tuberculous disease of the gland is found, however, in only a proportion of the cases. It has also been shown that deficiency of the cortex and not of the medulla is the essential cause of the disease. Its chief features, which closely resemble those seen in adrenalectomized animals, are: (a) muscular weakness and languor, (b) low blood pressure and reduced circulation rate, (c) gastro-intestinal disturbances, loss of appetite (anorexia), hypohydria and vomiting, (d) pigmentation of the skin and mucous membranes, bronzing, tanning or a dirty brown cutaneous discoloration being a classical symptom of the disease, (e) lowered metabolic rate, subnormal temperature, sodium loss and a rise in serum potassium, reduced blood volume (plasma loss), dehydration and loss of weight, (f) renal insufficiency with consequent rise in blood nonprotein nitrogen, (g) depression of the sexual functions, (h) hypoglycemia may occur

normal pigmentation is greatest (fig. 272). The palms of the hands and soles of the feet remain pale. The discoloration is due to the excessive accumulation of the normal cutaneous pigment, *melanin*. This is deposited chiefly in the basal cells of the epidermis, but pigment granules are also found in the dermis. The change in pigment metabolism which causes the deposits is unknown.⁷ Szent-Györgyi found that ascorbic acid which, as already mentioned, is present in relatively high concentration in the adrenal cortex inhibits pigment formation in plant tissue but it remains to be shown that a lack of this substance in Addison's disease is responsible in any way for the bronzing.

Addison's disease unless treated with cortical hormone or with a diet of high salt and low

⁷ Bloch found that sections of normal skin became deeply pigmented when placed in a dilute solution of 3:4 dioxypyphenylalanine; albino skin treated similarly remained unpigmented. Solutions of other aromatic compounds (e.g., tyrosine, tryptophane, pyrogallol, etc.) did not cause pigmentation of skin sections. Bloch concluded that *dioxypyphenylalanine*, which he called *dopa*, was the precursor of melanin, the conversion being brought about by an oxidizing enzyme (*dopa oxidase*) in the skin. A theory to account for the excess pigment of Addison's disease has been formulated upon the basis that *dopa* is a likely intermediary in the formation of adrenaline from tyrosine. In deficiency of the cortex it is postulated that a greater amount of *dopa* is converted to melanin and less into adrenaline. Thus

and be the immediate cause of death. The pigmentation may be so deep as to cause the patient to be mistaken for a mulatto; it is most pronounced in those regions, nipples, abdomen, etc., where the

This theory implies that the adrenal cortex is concerned in the production of adrenaline from a precursor. There is no evidence, however, that the cortex possesses this function, and it is even a matter for speculation whether or not *dopa* represents a stage in the formation of adrenaline (see p. 685).

potassium content, is almost invariably fatal within from 1 to 3 years. Unfortunately, the results of treatment are not uniformly good. In some subjects the course of the disease is apparently little altered by treatment. In others, however, remarkable improvement takes place. Patients, even in a collapsed or comatose state, have been brought back to health by administration of the hormone aided by a diet suitably adjusted as to its mineral constituents. The pigmentation fades, often rapidly, the metabolic rate and the blood pressure rise, and the strength returns. As an illustration of the almost specific action of salt in the treatment of Addison's disease the following case reported by Loeb and his associates may be cited. A female patient upon a high salt diet was able to be up and about the

FIG. 272. Showing pigmentation of the skin together with patches of depigmentation in a patient with Addison's disease. (After Loeb.)

ward. When her salt intake was restricted to 2 grams daily she was so weak by the end of the first day that she had to remain in bed; by the next day there were nausea and extreme prostration. Rapid improvement followed when the salt intake was restored to its original level. It follows that in cases in which a diagnosis of Addison's disease is in doubt important assistance will be afforded by noting the effects of a high and a low salt intake, respectively, upon the patient's condition. This in essence is the so-called *provocative test* of Wilder and his associates.

Cortical tumors—adrenogenital syndrome, pseudohermaphroditism

Tumors composed of cortical tissue may arise in the adrenal itself or in aberrant collections of cortical cells (adrenal "rests") which are found

in the broad ligament of the uterus, in the neighborhood of the testes or in the retroperitoneal tissue of the abdomen or pelvis. Such growths may occur in children or in adults, and are associated with extraordinary abnormalities of development especially of the *accessory organs of sex* and of the *secondary sex characters* (p. 743).

When these growths occur in young children puberty appears prematurely; a male child of 4 or 5 years, for example, may show the sexual development of an adult (fig. 273). The testes and penis are enlarged, hair may appear upon the chest, pubis and face, and there may be precocious sexual desire. There may also be unusual muscular development or extreme obesity. Children

FIG. 273. Enlarged abdomen and precocious sexual development of a boy aged thirty months. A mass palpated in the abdomen was probably a suprarenal cortical tumor. (After Rowntree and Ball.)

showing these characters have been described as resembling "an infant Hercules" (Herculean type of Weber), or "a burly brewer's drayman" (Guthrie). Growth is rapid as a rule, but the epiphyses fuse early; young subjects of the disease therefore do not reach full stature.

In little girls the breasts hypertrophy, hair appears on the mons veneris and around the vulva; the uterus develops prematurely, the clitoris hypertrophied and menstruation may occur. In appearance such children resemble stout little women. Adult women who are subjects of the disease become mannish in appearance and disposition (virilism, fig. 274). The voice deepens, menstruation ceases, the breasts atrophy and

hair may grow upon the face, chest and limbs; homosexuality is a common feature. The urinary excretion of androgens is greatly increased. The nature of the effects upon the female sexual processes therefore differs in accordance with the age at which the disease makes its appearance. In some adult female subjects, the virilism is accompanied by glycosuria and decreased sugar tolerance. This type is known as the Achard-Tiers syndrome and was described by these authors as the "diabetes of bearded women." Adult

According to Broster and Vines, many cases of virilism are associated with a diffuse hyperplasia of the adrenal cortex rather than with a definite tumor of cortical tissue. These observers have made the interesting discovery that the hyperplastic or tumor tissue contains large numbers of cells which have an affinity for fuchsin (fuchsinophil cells). Cells possessing this property are normally absent from the mature adrenal or present only in very small numbers. They are a characteristic feature, however, of the fetal adrenal of both sexes between the 10th and 17th weeks (in the case of the male) and between the 11th and 15th weeks

FIG. 274. Virilism due to adrenal tumor. In center, at age of 28 years before the onset of the disease; on right, at age of 35 years at height of disease. (After Lescher.)

female subjects of cortical tumors, as a rule, give no evidence of endocrine disturbances. In some, however, an exaggeration of the masculine characters is manifest, e.g., enlargement of the penis, a tendency to hirsutism and increased sexual appetite. More commonly, a certain degree of feminization is observed, e.g., enlargement of the mammae, atrophy of the testes and a feminine distribution of fat. In some cases of cortical tumor the clinical picture closely resembles that of pituitary basophilism (p. 737).

(in the case of the female) but disappear thereafter. These observers suggest that virilism is due to the elaboration of a masculinizing hormone by the fuchsinophil cells, and that the female fetus normally passes through a male phase.

Surgical removal of a tumor of cortical tissue may be followed by acute adrenal insufficiency. Such a phenomenon is analogous to the hypocalcemia which follows removal of a parathyroid tumor (p. 709) and illustrates the general principle, which is also exemplified in some cases of thyroid adenoma, that the secretion of a normal endocrine organ is inhibited by that derived from another source (e.g., neoplasm or injection).

CHAPTER LX

THE PARATHYROID GLANDS AND CALCIUM METABOLISM

THE PARATHYROIDS

Development and structure

These glands were first recognized as separate structures and described by Sandstrom (1880). He gave them their present name in the belief that they were remnants of embryonic thyroid tissue. They arise, however, quite independently of the thyroid from the entodermic lining of the III and IV visceral clefts in close association with the origin of the thymus. Nor have they any known functional relationship with the thyroid. The parathyroids are usually stated to be four in number, two in relation to the dorsal surface of each thyroid lobe. The upper one on each side is called the "external" or "parathyroid IV." It lies near the upper pole of the thyroid and is often embedded in the latter's substance. The lower one—the "internal" or "parathyroid III"—is situated near the lower pole of the thyroid or at a variable distance below this level. It is drawn into a position below (caudal to) parathyroid IV in early embryonic life. The number of parathyroids and their positions are, however, very inconstant, in man as well as in animals, and accessory parathyroid tissue may be found anywhere in the neck or even in the thorax embedded within the thymus. The Roman numerals III and IV refer to the gill-cleft from which the gland arose. The terms "internal" or "external" signify the proximity of the gland to the mesial or to the lateral aspect, respectively, of the thyroid lobe. The human parathyroids are roughly oval in shape, and about 6 mm. in length.

The parathyroid tissue is composed of large round cells, closely packed into masses separated by capillary sinuses; the cells show no alveolar arrangement; in the adult gland they are of two main types. (a) *Clear chief cells*. These have large nuclei; the protoplasm stains poorly and is usually non-granular. These cells are, apparently, the essential secreting cells of the gland, since they are the only ones present in the human gland up to the 10th year, and at any age in some animals, e.g., the dog. (b) *Oxyphil cells*. These are larger than the preceding and contain granules in their cytoplasm which stain with eosin. They do not appear in the human gland until after the 10th year and are entirely absent from the glands of the dog.

The *blood supply* is very rich and derived from branches of the *inferior thyroid artery*. The *nerve supply* is scanty and the fibers are probably entirely vasomotor in character. They have the same origin as those innervating the thyroid. Secretory nerves have not been demonstrated. The functional activity of the parathyroids is possibly controlled by a hormone liberated by the anterior lobe of the pituitary (p. 728).

THE EFFECTS OF PARATHYROIDECTOMY— HYOPARATHYROIDISM

The small size of the parathyroids in laboratory animals and the fact that they are often embedded in the thyroid make their separate removal by operation very difficult if not impossible. The usual experimental procedure is to remove the thyroid. When this is carried out upon cats or dogs a sufficient proportion of parathyroid tissue is usually removed along with the thyroid to produce urgent symptoms of parathyroid deficiency. These symptoms constitute the condition known as *tetany*. Since tetany may be produced in other ways (see below) the condition when induced by parathyroid removal is called *parathyroid tetany* or *tetania parathyreopriva*. Tetanic symptoms do not, however, invariably result from complete thyroidectomy. The failure of symptoms to appear is due most likely to the presence of accessory parathyroid tissue, or to one or more of the four glands having been left behind, since it is not unusual for a parathyroid, especially one of the lower pair, to be situated a short distance from the thyroid. A description of the tetanic state is given on p. 702.

In general, young animals are more susceptible to the effects of parathyroid deprivation than older ones. A meat diet also appears to increase the susceptibility. But apart from the factors of age and diet the severity of the tetanic manifestations and the time of their appearance after thyroparathyroidectomy vary greatly in different species and between different individuals of the same species. This variability is also in many cases due to differences in the amount of accessory tissue which exists or to the inconstancy in the position of the glands. In the rabbit, for example, the internal (lower) parathyroids usually lie below the thyroid and unless these are sought for and removed tetany does not, as a rule, develop. Tetany is induced in the rabbit with difficulty by thyroparathyroidectomy, yet the condition can be readily induced by other means (p. 702). In cattle also this operation is not followed by tetany.

In the human subject tetany sometimes follows thyroidectomy for goiter, or for malignant disease, and is then due to the inadvertent or unavoidable

removal of the parathyroids (*post-operative tetany*).¹ The removal of a parathyroid tumor is also frequently followed by tetany (p. 708). Some of the earliest reports of tetany following thyroidectomy came from the surgical clinics of Kocher at Berne, and Reverdin at Geneva. The tetanic symptoms were then ascribed to infection of the operation wound (Kocher) or to thyroid deficiency (Reverdin). Though the parathyroids had been described only a few years previously by Sandstrom, their functions were unknown until the experiments of the French physiologist Gley who

rarely, in adults as a result of defective parathyroid function. Tetany arising in this way does not differ essentially from that following parathyroidectomy. The tetany of infants is usually, however, an accompaniment of rickets and, so far as is known, is then not due to parathyroid deficiency. During the active stage of rickets the serum calcium is little if at all depressed, but during the healing stage of the disease calcium is diverted to the bones and the calcium of the serum falls. It is at this time that tetany occurs (p. 703). Tetany may also be produced in rachitic rats by

in 1892, established the fact that their removal was the cause of the tetanic seizures which followed operations for goiter.

OTHER FORMS OF TETANY

These with the chief changes in blood chemistry are shown in table 68.

Infantile and idiopathic tetany

Tetany occasionally arises spontaneously in infants and may then be due to parathyroid deficiency. Spontaneous, or idiopathic tetany as it is sometimes called occurs also, though

¹ It is not very unusual for mild symptoms of tetany to occur after operation but to disappear later. These are probably due to injury and a temporary functional derangement of parathyroid function.

placing them upon an antirachitic diet (Hess and associates).

The tetanies of osteomalacia and sprue

Osteomalacia is a disease of the bones of adults (p. 656). Its pathogenesis is essentially the same as that of rickets. The serum calcium is often very low; tetany is of common occurrence. Tetany occurs in *celiac rickets and non-tropical sprue* (see p. 657). In the latter disease the absorption of fat and of calcium is defective and the serum calcium depressed. Tetany also sometimes occurs in tropical sprue.

Tetany associated with alkalosis (gastric, hyperpneic, and bicarbonate tetany)

In pyloric obstruction, dilatation of the stomach, or as a result of persistent vomiting from other

causes, the loss of chlorine in the vomitus causes a change in the acid-base balance toward the alkaline side. Tetany follows. Alkalosis is also the apparent cause of the tetany which results from increased pulmonary ventilation. In this case it is the excessive elimination of carbon dioxide which is the cause of the increased blood alkalinity. Collip has suggested that the muscular "cramps" which occur while swimming may be due to the hyperpnea induced by the cold water. Alkalosis is also evidently the cause of the tetany-like seizures which sometimes follow the administration of large quantities of sodium bicarbonate for therapeutic purposes (see also p. 704).

Phosphate tetany

Phosphate tetany is produced experimentally. The intravenous injection of 0.5 gram per kilogram of either the acid or the alkaline sodium (or potassium) phosphate into animals causes a profound and rapid fall in the serum calcium. In dogs, it is only after the injection of the alkaline salts, however, that tetany occurs.² This difference is probably due to the different effects of the two salts upon the acid-base balance—the one tending to cause alkalosis and a reduction in the ionization of calcium, the other acidosis and a relative increase in the concentration of calcium ions (see below). The injection of a neutral mixture of the two salts or of phosphoric acid itself does not cause tetany.

Citrate tetany

An intravenous injection of sodium citrate is a less sure way to induce tetany, but in a certain proportion of animals typical convulsions follow within 15 or 20 minutes after the injection. The serum calcium is lowered.

Tetany due to calcium and vitamin D deficiency

After a period of from 3 to 7 weeks on a diet lacking in calcium, the serum calcium of rats falls to a low level but tetany does not develop unless the diet is also devoid of vitamin D. Even when both calcium and vitamin D are absent from the diet, tetany does not appear spontaneously, but typical convulsive seizures can be induced by stimulation with the galvanic current or by a sudden sound.

MILK FEVER. Hypocalcemia and tetany sometimes occur in cows after calving as a result of the loss of calcium in the milk. The condition is treated by inflating the udder with air, which suppresses milk secretion and causes a rise in the serum calcium, or by

the intravenous injection of calcium. A similar condition is seen in sheep after lambing and is then referred to as "lambing sickness" or "ewe distemper."

Magnesium-deficiency tetany

The general features of this type of tetany are indistinguishable from those due to calcium deficiency. It has been produced in rats, dogs, and young cattle on feeding diets deficient in magnesium. Calves reared upon the whole milk, which has a low magnesium content (0.01 per cent), frequently show severe tetany and may die in convulsions. The blood calcium and phosphorus are within normal limits but the magnesium is reduced to little more than half the normal value. This type of tetany is not known to occur in the human subject.

A GENERAL DESCRIPTION OF THE TETANIC STATE

A. In animals the tetany following parathyroid extirpation has been studied most extensively. Its chief features are: (a) *fall in serum calcium* from the normal level of from 10 to 12 mg. p. 100 cc. to 6 mg. or less. The fall may be very abrupt, reaching the latter value in twenty-four hours, or may be delayed for from forty-eight to seventy-two hours or so. (b) *Rise in inorganic phosphorus of the plasma* from a normal of around 5 mg. per cent to between 6 and 8 mg. or more. (c) *The urinary excretion of calcium and phosphorus is reduced.* (d) *Rapid noisy breathing*³ (100 or more per minute), *high temperature* (104° to 105°F) and *tachycardia*. (e) *Salivation*, often with frothing at the mouth. (f) *Fibrillary twitching of the muscles* followed by *tonic or clonic (jerking) muscular contractions*. The jaws are clenched and the limbs are either stiffly extended or jerked violently; the head is dorsi-flexed. Sometimes there are automatic swimming-like movements of the fore-limbs in dogs, or, in cats, rhythmic jerking movements of the paws, as though the animal were trying to shake water or some other material from them. (g) The muscles show *increased excitability* to the galvanic current (p. 703) and to mechanical stimulation. Normally 6 milliamperes are required to produce cathodal opening contraction (C. O. C.) when the electrode is applied to the skin over the muscle and its nerve. In the tetanic state less than 1 milliampere may be sufficient. The time constant of accommodation is increased (see p. 783). (h) It has been shown by Imrie and Jenkinson that the *phosphocreatine* of the muscles is reduced and

² In rats, according to the results of the experiments of Greenberg and his colleagues, tetany follows the intravenous injection of the di-sodium salt.

³ The increased pulmonary ventilation, by blowing off carbon dioxide and producing a condition of alkalosis, no doubt increases the severity of the symptoms (see tetany of hyperpnea).

rate of resynthesis slower than normal. (h) *Death usually occurs from asphyxia*, due to spasm of the laryngeal and thoracic muscles.

The tetanic symptoms are closely related to the serum calcium level. As this becomes lowered the symptoms, mild at first (perhaps merely slight stiffness of the hind-limbs), become gradually more severe and when the serum calcium has fallen to between 5 and 6 mg. per cent, the tetanic state is usually fully developed.

Parathyroidectomized rats show an increased appetite for calcium; when given a choice between a calcium solution and water they drink more of the former than do normal rats under the same circumstances. As compared with normal animals they drink less of a phosphate solution.

B. In man. In adults, tetany is most frequently due to parathyroid deficiency—the result of an operation for goiter or for the removal of a parathyroid tumor (p. 708). The symptoms are usually less intense than those seen in parathyroidectomized animals, the condition, as a rule, running a more chronic course. Rapid respirations and high temperature are not common features. The serum calcium does not, as a rule, fall below 7 or 8 mg. per cent. Neuromuscular hyperexcitability is the outstanding feature. Though jerking movements or generalized convulsions may occur in children they are unusual in adults. The hypertonic state of the muscles causes the hands and feet to be drawn into typical attitudes which are spoken of as *carpo-pedal spasm* (fig. 275). The hands are flexed at the wrists, and the fingers flexed at the metacarpo-phalangeal but extended at the interphalangeal joints. The thumb is adducted into the palm. This position constitutes the so-called *accoucheur's hand* of tetany. The feet are extended at the ankles and the toes plantarflexed. Spasms of the eye-muscles may be seen, and occasionally spasmodic retention of urine occurs. In infantile tetany spasm of the muscles of the glottis is not uncommon, causing inspiratory stridor (*laryngismus stridulus*). When severe, the laryngeal spasm causes complete closure of the glottis for a time; cyanosis results and when asphyxiation seems imminent a sharp inspiration occurs accompanied by a high-pitched "crowing" sound. These various forms of muscular spasm are grouped under the general term *spasmophilia*.

Latent tetany

Frequently the serum calcium remains just above the critical level at which definite tetanic

symptoms appear. Emotion, some undue strain upon the organism, e.g., pregnancy, lactation or a failure in general health, may, however, precipitate an attack of manifest tetany in a subject who had been suffering from the disease in latent form. Certain tests are employed to uncover this incipient form of the disease: (a) *Chvostek's sign*,—tapping over the facial nerve in front of the ear causes

FIG. 275. Tetany. Description in text. (Upper photograph after Purvis Stewart; lower, after Cabot.)

twitching or spasm of the facial muscles. (b) *Trousseau's sign*,—obstruction of the circulation in the arm by means of blood-pressure armlet causes the hand to assume the typical attitude. The effect is probably due to the anoxemia induced in the muscles of the hand and forearm. (c) *Erb's sign*,—increased excitability of the muscles to the galvanic current already referred to.

PATHOGENESIS OF TETANY

MacCallum and Voetglin discovered that the serum calcium was invariably depressed in tetania parathyreopriva and that the condition was immediately relieved by the intravenous injection of calcium.

With the general recognition of these facts the *calcium deficiency theory* came into being. The low serum calcium found in other forms of tetany, of tetany produced otherwise than through parathyroid deficiency, e.g., the tetanies of rickets, osteomalacia and sprue, also indicates that calcium deficiency is the direct cause of the neuro-muscular hyperexcitability in these conditions. Depression of the serum calcium also explains the convulsions following the injection of phosphate. It is generally accepted that the determining factor in the production of tetany is the concentration of *ionized* calcium (p. 710) in the plasma and extracellular fluids of the body, rather than the *total* calcium concentration. For example, in nephritis with a low serum protein, the total calcium of the serum may be reduced to 3 or 4 mg. per cent, yet tetany does not occur, presumably because the concentration of ionic calcium has not been reduced to the critical level. As shown by the experiments of Loeb upon frog muscle the sodium and potassium ions tend to increase neuromuscular excitability, the calcium and magnesium ions to depress it. The calcium concentration of the tissues themselves (muscle or brain) is not altered in tetany, the increased neuromuscular excitability would therefore appear to be due to an imbalance between the concentration of ionic calcium in the extracellular fluids and within the tissue cells. (See also p. 706.)

It is difficult to assess the importance of hyperphosphatemia as a factor in the production of tetany, for a reciprocal relationship exists in the blood between the concentrations of calcium and phosphorus. Phosphate retention or phosphate injection causes a fall in the calcium of the serum; a rise in the concentration of the calcium of the serum, on the other hand, tends to depress the blood inorganic phosphorus. Nevertheless, tetany can result from a reduction in the serum calcium as in infantile rickets and osteomalacia with a normal concentration of blood phosphate. Hyperphosphatemia, therefore, though undoubtedly increasing the severity of the tetanic symptoms does not appear to play the primary rôle in their development.

The tetany of alkalosis is not easy to explain

upon the basis of calcium deficiency, since in this type the serum calcium is not significantly lowered. It is suggested, however, that the shift of the acid-base balance of the blood toward the alkaline side causes a reduction in the ionic calcium fraction without altering the concentration of the total calcium of the serum. The following equation illustrates the possible relationship between the concentrations of calcium, bicarbonate, phosphate and hydrogen ions.

$$\frac{[\text{Ca}^{++}] [\text{HCO}_3^-] [\text{HPO}_4]}{[\text{H}^+]} = K$$

According to this equation an increase in the concentration of the bicarbonate ions or of phosphate ions or a fall in the concentration of hydrogen ions would cause a reduction in the concentration of ionized calcium without a change in the total calcium level of the serum.

This conception has not been fully tested in direct experiment owing to the lack of a convenient and reliable method for determining the ionic calcium fraction of the serum (p. 710). Certain observations, however, are in conformity with such a hypothesis. The beneficial effect upon tetany of the administration of an acidifying salt such as ammonium chloride, since it is not accompanied by a rise in the total calcium of the serum, and the difference, already mentioned between the actions of the alkaline and acid phosphates (p. 702), may be explained upon such a basis.

It should be borne in mind, however, that the condition known as tetany is simply the manifestation of neuromuscular excitability. It is conceivable that abnormal conditions other than calcium deficiency may alter the excitability of the cells. In other words it need not be assumed that all forms of tetany are due to a common cause.

The question of the neuromuscular mechanism responsible for the tetanic seizures has not received a decisive answer. D. N. Paton and his associates sectioned the cord in parathyroidectomized dogs and observed cessation of the clonic and tonic spasms, but the tremors and the fibrillary twitchings were abolished only by section of the peripheral nerves. The results indicated that the tonic and clonic spasms were supraspinal in origin while the finer movements were dependent upon spinal centers. West more recently concluded that the supraspinal centers were not involved since the characteristic tonic and clonic spasms persisted after section of the cord in the upper thoracic region. The integrity of the spinal reflex arc was

however, considered to be essential for the tonic and clonic manifestations since they were abolished after section of the dorsal roots. The fibrillary movements and the increase electrical excitability of the muscles thus appeared to be dependent upon a peripheral mechanism. They persisted for at least 24 hours after section of both afferent and efferent nerves. In contradiction of West's conclusions, Greenberg and his colleagues state that in rats, tetanic movements of the hind limbs but not of the forelimbs are abolished by transection of the cord at the level of the 7th spinal segment. They conclude that activity of nervous centers above the spinal level is essential for the development of both the tonic and clonic seizures.

TREATMENT OF TETANY

Though the tetanic symptoms are rapidly abolished by the intravenous administration of calcium salts, the beneficial effect is of short duration. Calcium by mouth is of little value in acute tetany, but is of some value in the more chronic forms. Acidifying salts, e.g., ammonium chloride are also of benefit. A single injection of parathyroid extract will relieve the condition in a few hours and hold it in abeyance for several days. In chronic tetany (e.g., post-operative) irradiated ergosterol in the form of dihydrotachysterol or calciferol is of great value, especially when combined with a high calcium and a low phosphorus intake. According to Anderson and Lyall adjustment of the calcium and phosphorus of the diet (0.5 to 0.65 gm. of phosphorus, daily) is capable alone of controlling the symptoms.

THE ACTIONS OF PARATHYROID EXTRACT

The belief in the calcium-regulating function of the parathyroids, which followed naturally upon the discovery that hypocalcemia was an accompaniment of parathyroid deficiency, received spectacular confirmation in 1925. In this year Collip obtained an extract from beef parathyroids which possessed a powerfully hypercalcemic effect.⁴ By the intravenous or subcutaneous

⁴The extract was obtained by boiling fresh glands for 1 hour with 5 per cent HCl. The resulting liquid after cooling was made alkaline to pH 8 by the addition of NaOH. Hydrochloric acid was then added slowly until a maximal isoelectric precipitation of protein occurred. The precipitate was removed by filtration or centrifuging. The filtrate or supernatant fluid contains the active principle. The potency of the extract was assayed upon dogs, a unit being defined as $\frac{1}{100}$ th of the quantity of extract which will cause a rise of 5 mg. per cent in the serum calcium of a 20 kilogram dog within a period of 15 hours. The extract, for which the name "parathormone" was suggested by Collip, is usually sold in 5 cc. vials and has a potency of 20

administration of this extract to parathyroidectomized dogs the serum calcium can be maintained at the normal level. Violent tetanic symptoms are abolished within three or four hours after the injection of 10 or 20 units, and by the daily administration of considerably smaller doses than this the animal is maintained in good health indefinitely. If after the calcium has been raised to normal the administration of the hormone is continued in frequently repeated doses (10 to 20 units twice daily or oftener) or if given in such dosage to a normal animal, overdosage effects are produced. These are, (a) *Early changes in blood chemistry*. The serum calcium rises abruptly and within from twenty-four to forty-eight hours usually reaches a concentration of from 18 to 22 mg. per 100 cc. (fig. 276). During this time the inorganic phosphorus shows a moderate fall followed by a return to normal and a small rise. There is a slight rise in the potassium and magnesium of the serum. (b) *Early symptoms*. During the rise in serum calcium there are loss of appetite, depression and weakness, polyuria, vomiting, diarrhea and dehydration. (c) *The urinary excretion of calcium and phosphorus* is greatly increased. The increased excretion of phosphorus precedes the rise in serum calcium and the increase in urinary calcium. There is little change in the fecal excretion of these elements. (d) *Late blood changes* are; a reduction in the hypercalcemia by 2 or 3 mg. per cent; a pronounced rise in the plasma inorganic phosphorus; a four-fold increase in blood nonprotein nitrogen; a reduction in blood volume by 15 per cent due to plasma loss and, in consequence, concentration of the blood and, a great increase in its viscosity. (e) *Late symptoms*. At the time that these blood changes are occurring urgent symptoms appear,—vomiting of bloody fluid and sometimes the passage of blood-stained stools; signs of renal failure; great prostration ending in death. (f) *At autopsy* the gastro-intestinal mucosa is found to be the seat of extensive hemorrhages, and the stomach and upper part of the intestinal canal contain a quantity of bloody fluid.

The preceding description applies chiefly to dogs. The serum calcium of herbivorous animals, rats, mice, rabbits and guinea pigs, responds much less readily to the extract and the post-mortem picture so characteristic of its effects in dogs and cats, is not seen. In herbivorous animals, on the units per cc. It is effective by intravenous or subcutaneous injection, but is practically inert when given by mouth.

other hand, repeated doses cause the deposit of calcium in the soft tissue (metastatic calcification), particularly of the arterial tree; this is infrequent in dogs. In the human subject hypercalcemia is produced about as easily as it is in dogs. In both man and dogs tolerance to the hormone not infrequently becomes established after a certain number of doses.

The excess calcium in the serum following parathormone overdosage is derived from the skeleton. Bauer, Aub and Albright have shown that repeated doses of the extract to rabbits causes a reduction of the trabeculae of the epiphyses indicating that they serve as a store of calcium, which is rapidly mobilized by the hormone (fig. 277). By the administration of parathormone over long periods a condition corresponding to

level in the blood was conceived to depend upon "series of interlocked equilibria between this compound and inorganic calcium ions." Increase in the concentration of the organic compound in the blood caused corresponding increase in ionic calcium which was furnished by the bones (see also p. 713). After parathyroidectomy conditions were reversed, a fall in concentration of the compound and reduction in ionic calcium resulted. Another view (Greenwald) was that the hormone itself, or a substance formed through its action, increased the solvent power of the plasma for calcium. This substance, designated X, was supposed to unite with calcium ions to form an undissociated organic calcium compound which was stated to resemble calcium citrate. By this action the concentration of calcium ions in the plasma was reduced and the concentration of undissociated calcium increased. Since the plasma was believed to be in equilibrium with solid tricalcium phosphate ($\text{Ca}_3(\text{PO}_4)_2$) of osseous tissue, a reduction in the calcium ion concentration of the

FIG. 276. Curves of serum calcium, blood phosphorus and non-protein nitrogen reproduced from Collip's article describing the effects of parathyroid extract. The curve representing the non-protein nitrogen is not from the same animal as are the curves of serum calcium and blood phosphorus.

osteitis fibrosa cystica of man (see below) has been produced by Bodansky and Jaffe in guinea pigs and by others in rats and puppies. Continued administration of the hormone to experimental animals results in gross and microscopical changes in the glands themselves; they become much reduced in size and their cells appear shrunken, show hydropic degeneration and a diminution in the number of mitotic figures. Such changes suggest that the administered hormone has depressed the functional activity of the glands.

The fundamental nature of the hormone's action has been subject of a considerable amount of discussion and no certain conclusion can be drawn. It has been thought by some (Cameron and Moorhouse) that the hormone controlled the formation of a specific non-diffusible organic calcium compound. The calcium

FIG. 277. Showing trabeculae of humeri of cat on (A) a high calcium diet, and (B) on a low calcium diet (Redrawn from Bauer, Aub and Albright.)

plasma resulted in the liberation of calcium ions from the bones. The result was a rise in the total calcium (dissociated plus non-dissociated) of the plasma. Little direct experimental evidence can be cited in support of either of the foregoing views. They picture the liberation of calcium from the bones as a physicochemical process. The histological studies of Selye and rats, on the other hand, suggest that the calcium mobilized by cellular activity. During the hypercalcemia the bony trabeculae showed large numbers of osteoclasts which are believed to be responsible for the removal of calcium. When the animal became tolerant to the hormone the osteoclasts were replaced by osteoblasts and the bone density increased, i.e., calcium was deposited. Schour and Ham, nevertheless, consider the appearance of osteoclasts to be the result of the resorption of calcium from the bone rather than that these elements are active agents. They point out that parathyroid administration interferes with calcification of the dentine of the incisors of rats though osteoclasts are absent.

Aub and his associates believe that the parathyroid hormone exerts its primary action upon phosphorus metabolism, the effects upon the metabolism of calcium being secondary to the depression of the inorganic phosphorus of the blood. Ellsworth suggests that the essential action of the hormone is to lower the renal threshold for phosphate, presumably by inhibiting reabsorption of the latter. The sequence of events, according to these views, are increased excretion of phosphorus, reduced inorganic phosphorus of the blood and a reciprocal rise in serum calcium. An observation which has some bearing upon this subject is the reported failure of the hormone to induce hypercalcemia in bilaterally nephrectomized animals. But the phosphate retention and the hyperphosphatemia which result from this operation might be expected to reduce or even prevent the hypercalcemic effect of the hormone, though the latter had no specific effect upon phosphorus metabolism. However, the important part played by the parathyroid hormone upon phosphorus metabolism cannot be doubted; but such action is probably separate from that upon the metabolism of calcium, for it is possible under certain circumstances to induce hypercalcemia by means of the hormone without causing a corresponding reduction in inorganic phosphorus (Thomson and Pugsley) and *vice versa*.

The liberation of the parathyroid hormone appears to be independent of nervous control. There is suggestive but no definite evidence that the output of the hormone is regulated by the anterior lobe of the pituitary through a parathyrotropic hormone (p. 726). A low level of serum calcium stimulates the liberation of the hormone by the glands, for when the thyroid-parathyroid apparatus was perfused with de-calcified blood and the perfusate injected intravenously into normal dogs, their serum calcium was raised from 1.3 to 4.9 per cent within 3 hours or less (Patt and Luckhardt).

Therapeutic uses of parathyroid extract

In *post-operative tetany* parathormone is of the greatest value in relieving urgent symptoms. It should be combined with large doses of calcium (40 to 60 grains daily of the chloride or larger doses of the lactate or gluconate) and with foods possessing a high calcium content, e.g., milk. Parathormone is generally considered unsuitable for prolonged administration, since it depletes the bones. Also, after a time, tolerance to its action frequently occurs. It would seem, however, to be a logical procedure to give the hormone in doses that would be just sufficient to replace the natural hormone which is lacking, together with large doses of calcium. Calcium chloride, since it supplies calcium directly and through its

acidifying action increases the ionic calcium is of great value. It may be combined with irradiated ergosterol.

In *lead poisoning* the metal is deposited in the bones as tertiary lead phosphate ($Pb_3(PO_4)_2$) displacing calcium from tricalcium phosphate ($Ca_3(PO_4)_2$). Parathormone mobilizes the lead from the bones and increases its excretion in the urine. Ammonium chloride and other acidifying agents have a similar effect. These salts are administered combined with a low calcium diet, which also encourages the mobilization of lead. According to Aub and his associates the increase in hydrogen ion concentration acts by converting the insoluble tertiary lead phosphate into the soluble di-lead salt. Caution should be exercised in the use of de-leading agents since serious effects may result from the sudden entrance of large quantities of the metal into the circulation. Toxic effects due to this cause are combated by a high calcium diet, which favors retention in the bones of the lead compound. When it is considered that the deposition in the bones of ingested lead is a device which protects the body from the toxic effects of the metal it is questionable whether it is desirable, as a rule, to employ de-leading agents. To remove the source of poisoning and permit the metal to be liberated spontaneously and gradually from the skeleton should be sufficient.

It has also been shown that radium deposits in bone may be liberated by parathormone and a low calcium diet.

Attempts to remove extra-skeletal deposits of calcium by means of parathormone have not met with success. This is not unexpected since the action of the hormone in mobilizing calcium and phosphorus is confined to the skeleton and may actually induce calcification of soft tissues (see p. 719).

There is a suggestion that *quite small doses* of parathormone may through the stimulation of osteoblasts encourage calcification, and thus may be of value in the treatment of delayed union of fractures.

THE RELATION OF VITAMIN D TO PARATHYROID FUNCTION

A number of observations suggest a relationship between the actions of *excessive dosage* of vitamin D and the parathyroids. The former, like parathormone, causes a high degree of hypercalcemia, and Hess, Weinstock and Rivkin found that in monkeys hypercalcemia is less readily induced by irradiated ergosterol after parathyroidectomy. Higgins and Sheard found that the parathyroids of chicks deprived of ultraviolet light became hyperplastic, but were restored to normal appearance by the administration of cod-liver oil. Taylor, Weld, Branion and Kay found that the toxic overdosage effects of irradiated ergosterol

were less severe than usual in dogs in which an operation for the complete removal of the parathyroid tissue of the neck had been performed. They also showed that the overdosage effects of parathormone and of irradiated ergosterol were similar. Both substances cause the same degree of hypercalcemia (fig. 278) and hyperphosphatemia, and a rise in the non-protein nitrogen of the blood. In large doses either causes the withdrawal of calcium from the bones and increases the excretion of calcium and phosphorus in the urine. The symptoms during life and the post-mortem findings after poisoning with either material are also identical, and those species (herbivora) resistant to parathormone are simi-

according to some observers increases the absorption of calcium from the intestine; parathormone exerts no such effect.

HYPERPARATHYROIDISM IN MAN. GENERALLY OSTEITIS FIBROSA CYSTICA

This is a condition of the bones which was described some years ago by von Recklinghausen. Though others had previously described this condition it is very often spoken of as von Recklinghausen's disease. The morbid changes in the bones are, decalcification, the formation of cyst-like cavities and resorption of the bony tissue of the trabeculae and shaft which become largely replaced by fibrous tissue (fig. 279). His-

FIG. 278. Serum calcium curve of a dog illustrating the effect of a large dose of irradiated ergosterol given intravenously in divided doses over a period of four hours. Note the prolonged effect upon the serum calcium. (A. Taylor, Weld, Branion and Kay.)

larly resistant to overdosage with irradiated ergosterol. It has been shown by others that either parathormone or irradiated ergosterol gives rise to metastatic calcification and to bony changes analogous to osteitis fibrosa cystica.⁵ Irradiated ergosterol, however, takes longer to show its effect upon the serum calcium than does parathyroid extract, and the hypercalcemia once established persists for some weeks (fig. 278).

Two other dissimilarities in the action of vitamin D and of the parathyroid hormone have been reported. Whereas, the hormone increases the reabsorption of phosphate by the renal tubules, vitamin D has the opposite effect. The vitamin,

⁵ Selye finds that the histological picture of the bone in the rat after parathormone differs from that resulting from overdosage with irradiated ergosterol.

logically a great increase in the number of osteoclastic elements (p. 714) is seen. The condition was shown by Mandl in 1926 to be due to adenoma of a parathyroid gland. Its chief clinical features are, (1) pain in the bones. (2) Hypotonicity of the muscles. (3) Elevation of serum calcium (sometimes up to 20 mg. per cent or but usually not above 15 or 16 mg.) (fig. 278) fall in plasma inorganic phosphorus (between 1 and 2 mg. per cent) and high plasma phosphate (4) Increase in urinary calcium, polyuria, high incidence of renal calculi; renal damage, peritubular calcium deposits leading to interstitial fibrosis, and cystic dilatation of the tubules (Anderson). The calcification appears to be secondary to a specific degenerative lesion. The mineral deposits in their turn induce further

damage of renal tissue. (5) Spontaneous fractures, deformity of the bones of limbs or spine, reduced and irregular density of the bones are evident under the X-ray. (6) A small tumor (parathyroid) may be palpable in the neck. In a case reported by Hunter a parathyroid tumor was found at operation behind the esophagus at the level of the second thoracic vertebra. In some instances the condition is due not to a single adenomatous tumor but to diffuse hyperplasia of parathyroid tissue (p. 729).

The treatment of the condition consists in locating and removing the tumor. The serum calcium falls abruptly after operation and frequently reaches a subnormal level; tetany of an intractable nature not uncommonly results. The cause of the abnormally low serum calcium is not easy to explain since it might be expected that the remaining healthy parathyroid tissue would be sufficient to maintain the serum calcium at the

in turn of phosphate retention and hyperphosphatemia (see renal rickets, p. 718).

CALCIUM METABOLISM

Calcium is an indispensable mineral; it is a constituent of all animal fluids and solid tissues; it plays an important rôle in a number of physiological processes and conditions. The most obvious of these are: (a) coagulation of the blood (p. 88), (b) formation of bone (p. 713), (c) cardiac rhythmicity (p. 158), (d) maintenance of normal neuromuscular excitability (p. 704), (e) milk production (p. 768), (f) membrane permeability (p. 25).

THE DISTRIBUTION OF CALCIUM IN THE BODY

Calcium constitutes about 2 per cent of the weight of the adult body and about 99 per cent of the total quantity is contained in the skeleton. The muscles contain about 8 mg. per 100 grams of

FIG. 279. Showing section of humerus from case of generalized osteitis fibrosa cystica. (From Hunter and Turnbull after Hill and Lucey.)

normal level. The phenomenon is probably due to the persistence after operation of a compensatory depression of activity in the other parathyroids which had resulted from the excess hormone discharged by the adenomatous gland. Bodansky and Jaffe found, for example, that in animals, hypocalcemia followed the termination of a prolonged course of parathormone injections.

Parathyroid hyperplasia may be induced experimentally by the following means (a) low calcium diet (rats and rabbits), (b) lack of vitamin D (chicks), (c) daily injections of phosphate over a period of weeks, (d) surgical reduction of renal tissue, or experimental nephritis; the former procedure produces dwarfing in rats and a condition resembling the renal rickets of children (Pappenheimer). In the human subject hyperplasia of parathyroid tissue may occur in association with chronic nephritis, in which event the parathyroid enlargement may be a compensatory reaction to the hypocalcemia which is the result

wet weight, plasma or serum from 9 to 11.5 mg. per cent. The red corpuscles contain only minute amounts; the content of the whole blood is,

FIG. 280. Showing chemistry of blood in hyperparathyroidism, and the effect of removal of the parathyroid tumor. (After Hunter.)

therefore, between 4.5 and 6 mg. per cent. The other body fluids, e.g., lymph, aqueous humor, ascitic and edema fluids, etc., contain it in some-

what lower concentration, while the concentration in the cerebro-spinal fluid is only about 5 mg. per cent. Negligible amounts of calcium are deposited in the skeleton before the fifth month of intra-uterine life, and over 60 per cent of the skeletal calcium of the new-born is the result of deposition during the last two months of prenatal life (fig. 281).

THE STATE OF THE CALCIUM IN THE BLOOD

Practically all the calcium of blood, as just mentioned, is contained in the plasma; after clotting it is all present in the serum, and it is upon this that determinations are usually made.

The clot itself contains mere traces. The calcium of blood exists in two forms, *non-diffusible* and *diffusible*. The non-diffusible form is bound to serum protein (chiefly to the albumin fraction). It remains in the serum when the latter is dialyzed or subjected to ultra-filtration (i.e., filtration of the serum through a collodion membrane by the application of hydrostatic pressure). The non-diffusible part constitutes about 45 per cent (from 4 to 5 mg. per 100 cc.) of the total serum calcium. The diffusible portion amounts to 55 per cent or so (5 to 6.5 mg. per 100 cc.) of the total calcium; when the serum is ultra-filtered this fraction passes into the filtrate. *Nearly all the diffusible calcium of the serum is in ionized form.* The previous low figures which have been given for the concentration of ionized calcium (1.5 to 2 mg. per 100 cc.) are, according to McLean and Hastings erroneous. They state that a very small amount of diffusible unionized calcium (about 0.25 mg. per 100 cc.) is present in the form of a citrate-like compound. The ionized calcium is in the form of calcium carbonate and phosphate. The following is a summary of the calcium fractions in serum.

Serum calcium:	mg. per 100 cc.
Non-diffusible.....	4.0 -5.0
Diffusible.....	5.0 -6.5
Ionized.....	4.75-6.25
Unionized	0.25

The non-diffusible calcium, as might be expected, varies with the protein concentration of the plasma. For example, in Bright's disease (without phosphate retention) the decline in serum calcium roughly parallels the fall in plasma albumin and the hypocalcemia is due mainly to a reduction in the non-diffusible fraction. Lymph which has a lower concentration of protein than plasma also has a lower calcium content.

The calcium of the cerebrospinal fluid, which is

practically protein-free, is almost entirely in the diffusible form, and has a concentration approximately equal to that of the diffusible fraction of the plasma. The calcium concentration of the cerebrospinal fluid has, therefore, been taken as an index of the diffusible fraction of the plasma calcium upon the assumption that the former fluid is simply an ultra-filtrate. This assumption is not warranted, since it is more probable that the cerebrospinal fluid is *secreted* by the choroid plexus (p. 933). Also, the administration of parathyroid extract or the injection of calcium salts, both of which raise the diffusible calcium of the plasma, causes little increase in the calcium concentration of the cerebrospinal fluid; it is little affected by parathyroidectomy.

McLean and Hastings have devised a biologic method for the determination of the ionized calcium of body fluids based upon the sensitivity of the frog's heart to the calcium ion concentration.

FIG. 281. Showing the increase in the calcium of human fetus in later months of gestation. (From Hastings after Schmitz.)

In this method the amplitude of the contraction of the isolated heart is recorded upon a moving drum. A cannula (a modified Straub cannula) is passed through the aorta into the ventricle and tied in position. A series of calcium chloride solutions graded in concentration by 0.1 millimoles per liter is made up. The cannula is filled with the unknown fluid (serum, edema fluid, cerebrospinal fluid, etc.) and the amplitude of the heart contraction recorded. The cannula is then emptied and refilled with one of the standard solutions. If the amplitude of contraction given with the latter is greater than that given by the unknown solution a standard solution of lower concentration is tried, if the contraction amplitude is less the cannula is filled with a more concentrated solution. The calcium solution giving a contraction which just matches that given with the unknown fluid is taken as having the same concentration as the unknown.

McLean and Hastings state that the ionization of calcium in the body fluids is determined primarily by an equilibrium between calcium and protein which may be expressed by the following equation:

$$\frac{(\text{Ca}^{++}) \times (\text{Prot}^{-})}{(\text{CaProt})} = K$$

$$= 10^{-3.22} \text{ (at a temperature of } 25^{\circ}\text{C. and pH 7.35)}$$

In other words, they consider that the calcium in protein-containing fluids is present as calcium proteinate which ionizes as a weak electrolyte into calcium and protein ions, with a residue of the protein-bound calcium, i.e., of the non-diffusible calcium fraction. They state that, knowing the protein and total calcium concentrations, the calcium ion concentration in human serum or other protein-containing body fluid may be calculated from this equation.

THE ABSORPTION AND EXCRETION OF CALCIUM— CALCIUM BALANCE

Calcium is found in food as both organic and inorganic compounds, but probably it is absorbed only in the inorganic form. Absorption occurs mainly from the upper part of the small intestine. The reaction of the intestinal contents is an important condition in the absorption of this mineral, its salts, for the most part being readily soluble in acid but insoluble in alkaline media. Sugars, especially lactose, which yield organic acids in the intestine, favour absorption. Fats (free from vitamin D) reduce calcium absorption on a high Ca, low P intake, owing most probably to the formation of insoluble calcium soaps; but for some reason, perhaps the production of soluble complexes with fatty acids, such fats increase the absorption of calcium on a diet with a low Ca/P ratio. Protein food tends to increase the absorption of calcium since the latter forms soluble complexes with certain amino acids. Soluble calcium salts, such as the chloride, carbonate, lactate, and gluconate, but not the relatively insoluble phosphate, are readily and, in moderate dosage, almost completely absorbed. After the ingestion of a large dose of a soluble calcium salt, the serum calcium level rises, reaching its maximum value in about two hours. The normal serum concentration is reached again about three hours later. It is not possible to maintain the calcium level above normal by the administration of calcium salts.

Milk is the best dietary source of calcium, but important amounts (up to 0.2 gram daily) of available calcium may be obtained from "hard" drinking water. The calcium of many vegetables

is well utilized by the rat; the calcium of carrots (and probably of certain other vegetables as well) is readily absorbed by the human intestine, being nearly as valuable as that in milk. Spinach and other plant foods containing oxalic acid, which forms a relatively insoluble compound with calcium, reduce calcium absorption. In cereals (wheat, oatmeal), owing to their content of phytic acid (inositolhexaphosphoric acid) which combines with calcium to form an insoluble salt, much of the mineral is unavailable. The action of phytic acid in the intestine may depress the absorption of calcium of other food materials. Whole wheat flour has a higher phytic acid content than has white flour and, therefore, is a poorer source of absorbable calcium. As mentioned elsewhere (p. 656), the phosphorus of phytic acid is also largely unavailable. These facts explain the decalcifying action of certain cereals.

FIG. 282. Front and side views of skeletons of twin brothers (albino rats), one of which had received a diet of normal calcium content (Wheat, meat, and milk) while the other had received a low calcium diet (wheat and meat). (After Sherman and MacLeod.)

Calcium is excreted into the small intestine and in the urine; little or none is eliminated through the wall of the colon. The excretion of calcium continues upon a calcium-free diet or during a fast and, under these conditions, the body is in negative calcium balance. In man, on an ordinary mixed diet the calcium of the feces amounts to from 0.4 to 0.8 gram; this, though partly endogenous, is mainly the unabsorbable calcium of the food.

Smaller quantities of calcium are excreted in the urine and about 150 mg. are lost daily by this route. An increase or decrease in the absorption of calcium is reflected in parallel changes in the urinary excretion. The urinary calcium constitutes, therefore, a convenient index of calcium absorption.

The *calcium balance*, that is the difference between the quantity of calcium ingested and that

excreted in the urine and the feces, is *positive* (calcium retention) during *growth*, *pregnancy*, *acromegaly*, or after a period of *calcium starvation*. Sherman and Hawley found that children from three to thirteen years of age, upon a daily calcium intake of from 0.74 to 1.02 gram of calcium, utilized (i.e., retained) from 0.15 to 0.62 gram per day; the quantity retained was in proportion to the size of the child (0.01 gram daily per kilogram). In adults, Breiter and his colleagues found that the utilization of the calcium of milk varied from 15.3 to 30.3 per cent. The calcium balance is *negative* in *infantile rickets*, *celiac* and *renal rickets*, *sprue*, *osteomalacia*, *hyperparathyroidism*, *hyperthyroidism* (pp. 675, 708), during *starvation* or *calcium deficiency*, and usually during *lactation*. In infantile rickets (p. 652), celiac rickets, and osteomalacia (p. 656), vitamin D administration reduces the negative balance, establishes calcium equilibrium or induces a positive balance. There is some uncertainty regarding the mode of action of vitamin D upon calcium absorption in normal animals. Some authorities believe that it increases the absorption of calcium but others maintain that its action in this regard is negligible and that its chief action is upon the deposition of calcium in the skeleton. Calcium metabolism is also influenced by vitamins A and C (p. 635 and p. 646). The daily calcium requirement and the calcium contents of various foods are given in chapter LVII, pp. 667 and 668, see also Fig. 282.

BONE

The composition of bone

Osseous tissue freed from fatty marrow is composed of organic material (mainly protein), water and minerals. The chief protein constituent is *ossein*, but there are also small quantities of *osseomucoid* and an *albuminoid*. Water constitutes about 25 per cent of the bone weight, organic material 30 per cent and inorganic constituents 45 per cent. The minerals consist of Ca, P, Mg, and small quantities of potassium, sodium, chlorine, fluorine and iron.

Calcium makes up from 15 to 18 per cent of the weight of fresh osseous tissue and from 20 to 25 per cent of the weight of bone which has been dried and extracted with ether.

Bone calcium exists in two forms, calcium carbonate— CaCO_3 —and tricalcium phosphate— $\text{Ca}_3(\text{PO}_4)_2$.⁶ The ash of bone amounts to about

⁶ Small amounts of calcium chloride and calcium fluoride are also present.

60 per cent of its dry weight. Calcium constitutes about 36 per cent of the ash, phosphorus about 16 per cent, magnesium 0.5 per cent and CO_2 5.5 per cent. The ratio of calcium to phosphorus is approximately 2.2 to 1. The ratio of *residual calcium* (i.e., calcium other than that present as carbonate) to residual phosphorus (phosphorus not combined with magnesium) is about 2 to 1. This is, approximately, the ratio of the two minerals in tricalcium phosphate. Magnesium is present mainly as $\text{Mg}_3(\text{PO}_4)_2$. The proportions of the three chief compounds in bone ash are $\text{Ca}_3(\text{PO}_4)_2$, 80 per cent, CaCO_3 , 13 per cent and $\text{Mg}_3(\text{PO}_4)_2$, 2 per cent. Some of the foregoing data are given in table 69.

Rickety bone contains a lower percentage of ash and larger proportions of water and organic material. The ratio of calcium to phosphorus, however, remains unchanged whether the rickety (experimental) develops upon a low calcium or a

low phosphorus diet. The magnesium content of bone is said to be increased in rickets and in osteomalacia.

It is now generally believed that the calcium carbonate and calcium phosphate of bone are present not as separate compounds simply mixed together with smaller amounts of other mineral salts, but as a complex compound.

From a comparison of the refractive indices and X-ray diffraction patterns of bone and dental enamel on the one hand, and certain crystalline minerals composed mainly of calcium and phosphorus, Taylor and Sheard have concluded that the inorganic solid phase of bone and dental enamel resembles the apatite series (podolite, dahllite, fluorapatite, etc.). Fluorapatite, which is nearest in chemical structure to bone salt, has the following formula, $\text{Ca}_{10}\text{Fe}(\text{PO}_4)_6$. The predominant compound in bone is *hydroxyapatite*— $\text{Ca}_{10}\text{OH}(\text{PO}_4)_6$ —, the Fe atom in fluorapatite being replaced by OH. The bone salt is laid down in the form of minute crystals. Compounds in

which sodium, magnesium and other minerals are substituted for Ca are also found in bone.

The ratio of total calcium to phosphorus, 2.2:1 (or 10 atoms of Ca to 6 of P) and that of residual calcium to residual phosphorus, 2:1, (9 atoms Ca to 6 of P) which exist in bone also support this conclusion.

Pathological calcifications, e.g., salivary calculi, arterial or pulmonary calcifications, are believed to be similar in chemical composition to bone. Hastings and his associates hold a similar view in respect to a crystalline compound related to the apatite series as being the main mineral constituent of bone.

It is perhaps well to point out that adult bone is not simply an inert structural material but living tissue whose mineral composition fluctuates under the influence of other body functions. The trabeculae of the bone, as shown by Aub and associates, constitute a calcium store readily available when necessary for the maintenance of the calcium requirements of other tissues when the exogenous supplies are deficient. For this reason, though calcium continues to be excreted when an animal is kept, even for a long period upon a calcium-free diet, no change in the serum calcium level occurs. Parathyroid extract, as mentioned elsewhere, raises the serum calcium through its action in mobilizing these calcium stores.

In birds, the extraordinary demand made upon calcium metabolism for the production of the egg-shell has been provided for by the development of osseous tissue within the marrow spaces of the long bones. Weakening of the essential skeletal structure which otherwise might result from the withdrawal of the mineral during the egg-laying season is thus avoided. The growth of this so-called *medullary bone* is stimulated by estrogens. Normally, its growth appears to be under the control of the ovarian secretion; it is cyclical or seasonal in character, and is associated with other phenomena of the mating season of birds, e.g., the appearance of serum vitellin in the circulation, an increase in plasma fat and phospholipid, and pronounced hypercalcemia.

The bones also serve a detoxicating function, elements such as lead, radium, fluorine and arsenic, being removed from circulation and deposited in the bones and teeth. "Mottled enamel" (chalky white patches upon the surfaces of the teeth) is attributed to an excess of fluorine in the food or drinking water, though smaller amounts of fluorine are said to be beneficial for the

development of the teeth and to prevent dental caries. The mobilization of bone calcium plays a very minor rôle in maintaining the normal blood reaction against the ingestion or production of excess acid. Some reduction in bone calcium can be detected, however, in animals after the administration of hydrochloric acid.

Bone formation

THE HISTOLOGY OF DEVELOPING BONE. There are two types of ossification, *intramembranous* and *intra-*

FIG. 283. Developing bone; proximal phalanx of a three-month human fetus. *kn*₁, unchanged cartilage; *kn*₂, columns of cartilage cells; *kn*₃, zone of calcifying cartilage; *kn*₄, vestiges of walls of broken down cartilage cavities; *ph*, perichondral (periosteal) bone (black); *ph*, perichondrium (periosteum);* connection between periosteum and primary marrow. As yet, no endochondral bone formation. (From Maximow and Bloom after Sobotta.) (See also p. 653.)

cartilaginous or *endochondral*. The bones of the cranial vault and the mandible are formed through the ossification of membranes. The bones of the limbs and trunk and the base of the skull are first modelled in cartilage which becomes transformed into bone by both endochondral and intramembranous (i.e., periosteal) forms of ossification. The development of a long bone of the limb, for example, starts with the deposition of calcium salts in the center of the shaft (*diaphysis*). From this *center of ossification*, as it is called, the process of calcification spreads toward each end of the bone (fig. 283). The cartilage cells just

ahead of the spreading zone of calcification show active proliferation, becoming arranged in longitudinal rows. The transformation of the calcified cartilage into true bone is brought about after the following fashion. The cells of the deeper layers of the membrane covering the cartilage—perichondrium—give off long processes to form a meshwork of interlacing fibers. These cells are referred to as *osteoblasts*. The fibrous framework thus laid down soon becomes impregnated with calcium salts with the formation of a layer of true bone just beneath the perichondrium, or periosteum as it must now be called. The subperiosteal process, which is essentially the same as that whereby the cranial bones are developed from membrane, is well advanced while the interior of the bone still consists merely of calcified cartilage. The latter, however, soon becomes invaded by blood vessels from the periosteum and by large multinucleated cells (20 to 40 μ) known as *osteoclasts*. These cells, which have a pronounced eroding action upon the mineralized cartilage, probably through the production of an enzyme, tunnel channels through it for the conveyance of the blood vessels and excavate small cavities. The excavations in which the osteoclasts lie are known as *Howship's lacunae*. Osteoblasts which have advanced into the interior with the blood vessels cause the formation of true osseous tissue in the walls of the spaces formed by the osteoclasts.

At a somewhat later date than that at which the primary ossification center appears in the shaft, a secondary or epiphyseal center appears in one or both ends of the bone. The calcification process and subsequent ossification follow the same course as that described for the diaphysis. The epiphyseal and diaphyseal areas, however, remain separated from one another by a layer of uncalcified cartilage, the *epiphyseal plate*, until a certain age, which varies between different bones.

Through the combined action of osteoclasts and osteoblasts a complete replacement of the calcified cartilage results and the structure characteristic of bone gradually evolves. The center of the shaft becomes hollowed out to form the medullary canal. The spaces which have been formed by the osteoclasts in the shaft of the bone itself become joined together and constructed into the system of *Haversian canals* which serve as conduits for the transmission of blood vessels. In the ends of the bones the spaces are much larger and irregular; and becoming filled with red marrow constitute the characteristic spongy or cancellous bone of this region. The walls of these spaces appear in cross section as interlacing bars of osseous tissue and are usually referred to as *trabeculae*. The bone forming the walls of the Haversian canals is laid down in a series of concentric tubular lamellae. As each lamella is completed it imprisons the osteoblasts within small lacunae from which numerous fine canals are given off; into these the processes of the osteoblasts penetrate. The osteoblasts in these situations lose their osteogenetic function but

do not disappear. In the developed bone they are referred to simply as *osseous cells* or *osteocytes*.

A long bone grows in length at the junction of the epiphyses with the diaphysis and in thickness through the activity of the osteoblasts of the deeper layers of the periosteum. The Haversian canals and the marrow cavity are also lined with a membrane—the *endosteum*—containing osteoblasts through which increased width of the bone is also brought about.

The osteoblasts and osteoclasts are concerned not only with the development and growth of bone, but are active throughout life and are responsible, it is believed to a large extent at any rate, for the lability of adult osseous tissue (p. 713). Healthy bone is constantly being broken down, resorbed and repaired. Several conditions may alter the balance one way or the other between these two processes, e.g., the relation of the calcium intake to the calcium requirement and the activities of various ductless glands—parathyroid, thyroid, pituitary, etc. Large numbers of osteoclasts are in evidence when bone resorption is taking place. Osteoclastic activity is therefore pronounced when remodelling of bone is occurring, as in the removal of excess callus or in the restoration to normal dimension of the enlarged end of a bone in healing rickets, in certain bone diseases, and in wasting diseases. In old age also, the resorptive process outstrips the processes of repair; the bones become rarefied (*senile osteoporosis*) and more fragile. Ham and some other authorities deny that the osteoclasts are active agents in the removal of the bone tissue, claiming that appearance of these cells is merely incidental or sequential to the resorption process.

When bone formation is in the ascendancy, as during the repair of a fracture, the osteoblasts show active proliferation.

Newly formed bone is stained selectively *in vivo* by madder, a red dye, or by alizarin, a derivative of it. These are therefore valuable agents for the investigation of the growth of bone in the living animal or of the action of parathyroid hormone and other influences upon bone metabolism. The dye, which is given orally is deposited with the mineral constituents, calcium and phosphorus.

A CONSIDERATION OF THE FACTORS UNDERLYING THE CALCIFICATION PROCESS. Several theories have been advanced in attempts to picture the processes underlying the deposition of calcium salts in the cartilaginous matrix. The four principal theories are as follows:

(1) A protein constituent of cartilage, it has been supposed, adsorbs calcium, for which it exhibits a special affinity; the calcium subsequently combines with phosphorus to form tricalcium phosphate. Wells showed, for example, that bone salts were deposited in a piece of boiled cartilage placed in the abdominal cavity.

(2) The saturation of a solution with a salt

such as calcium phosphate and the precipitation of the latter in solid form is determined by the product of the concentrations of the Ca^{++} and $\text{PO}_4^{=}$ ions in the solution, i.e., upon the *ion product* $[\text{Ca}^{++}] \times [\text{PO}_4^{=}]$; and not upon the total quantities of calcium and phosphorus present. The ion product at which the solution is just saturated is called the *solubility product*. The presence of protein in the solution reduces the degree of ionization, part of the calcium, as we have seen, becoming bound to form calcium proteinate, a weak electrolyte. The body fluids are therefore capable of dissolving more calcium phosphate than is a protein-free solution similar in its salt composition to that of plasma. The CO_2 dissolved in the body fluids also increases their ability to hold calcium salts in solution. Any reduction in the protein concentration or in the CO_2 tension in the body fluids would therefore be expected to favor the deposition of calcium salts.

An explanation of the calcification process upon a basis afforded by the foregoing considerations has been advanced by Howland. It is assumed that the fluids bathing the cartilage cells have, in common with other extravascular fluids, a lower protein concentration than has plasma. It is further suggested that since the cartilaginous matrix has a low metabolism, the CO_2 tension of the fluids bathing its cells is lower than that of plasma; the pH of these fluids will therefore tend to be higher. Such conditions it is argued must favor the deposition of calcium salts. A low concentration of inorganic phosphorus and of calcium in the plasma will, on the other hand, tend to retard calcification; this would be completely arrested if the ion product were below the value at which precipitation occurs. In practice Howland and his associates have employed the product of the *total* calcium and inorganic phosphorus, each expressed in milligrams per cent, as an index of the calcification process in infantile rickets. They state that in children with active rickets the product is practically always below 40, and when the disease is severe, below 30, whereas in normal children it is between 50 and 60 (i.e., $\text{Ca } 11 \times \text{P } 5 = 55$). It is obvious that a fall in either inorganic phosphorus or calcium would tend to lower the $\text{Ca} \times \text{P}$ product; actually two varieties of rickets were distinguished—a low phosphorus and a low calcium type. It is now recognized, however, that these are simply different stages of the disease and that the level of the inorganic phosphorus alone is a more useful

criterion by which to judge the extent of the calcification defect than the $\text{Ca} \times \text{P}$ product. For example, when rickets is progressing the inorganic phosphorus of the plasma is lowered to between 3 and 4 mg. or less per cent, but the serum calcium is not far from the normal level. During the stage of healing, i.e., of active calcification, the inorganic phosphorus tends to rise and the serum calcium to fall (p. 704); there might therefore be little change in the $\text{Ca} \times \text{P}$ product.

Another factor considered to be of importance in the calcification process is the *supersaturation* of the body fluids with calcium salts. That is, quite apart from the greater solubility of calcium salts in fluids containing protein and CO_2 , the concentrations of calcium phosphate and calcium carbonate in the body fluids are constantly maintained above their saturation limits, owing to the extreme slowness with which final equilibrium between the solid and liquid phases is established. Precipitation of these salts from solution will continue so long as the ion product is above that of the saturation level.

Calcification, however, cannot be explained upon a physico-chemical basis alone; the activity of living cells is also involved in the process. Shipley, Howland and Kramer showed, for example, that in experiments *in vitro* calcification was inhibited by a protoplasmic poison such as HCN. Two views have been expressed as to the nature of the vital processes concerned.

(3) Watt, from a comparison of the shapes of calcium phosphate particles precipitated in certain inert colloids with those formed in bone, concluded that calcification was not a simple precipitation of calcium phosphate from solution but was due to the active *secretion* by the osteoblasts of bone salts derived from the calcium and phosphorus of the blood.

(4) According to Robison and his colleagues, calcification is primarily dependent upon enzyme action through which the fluids in immediate relation to cartilage cells become highly supersaturated with calcium phosphate. These observers have accumulated much evidence in favor of their view. They have demonstrated the presence in bone (and also in plasma and other tissues, see below) of an enzyme capable of hydrolyzing various phosphoric esters, e.g., hexose-monophosphate, glycerophosphate, etc. This enzyme is called *phosphatase*. It is believed to be a product of the osteoblasts, the proliferating cartilage cells and the cells of the inner layer of the periosteum. According to this conception

of the calcification process the enzyme liberates inorganic phosphate from phosphoric esters and raises, locally, the concentration of the $\text{PO}_4^{=}$ ion. The product of the concentrations of the Ca^{++} and $\text{PO}_4^{=}$ ions then exceeds the solubility product of calcium phosphate, which is in consequence deposited in the cartilagenous matrix.

Evidence bearing upon this hypothesis is as follows:

(a) It was shown by Robison that when the head of a bone from a rachitic rat was immersed in a solution of calcium hexosemonophosphate at body temperature a deposit of calcium phosphate occurred in the zone of preparatory calcification (p. 653). This was attributed to the liberation by phosphatase of inorganic phosphate from a phosphoric ester, thus raising the product of the concentrations of $\text{PO}_4^{=}$ and Ca^{++} ions.

(b) Shipley, Kramer and Howland found that calcification of a rachitic bone occurred if placed in normal serum. Calcification also resulted if the bone were placed in a sterile solution of inorganic salts containing sodium chloride, sodium bicarbonate and magnesium sulphate, together with calcium and inorganic phosphate in the same concentrations as in normal serum. They concluded that living processes were concerned, since calcification was inhibited by HCN. They believed, however, that phosphatase could have played no part in the process for the artificial solution did not, of course, contain a phosphoric ester.

(c) Robison claimed that the result of the experiment just described was dependent upon the fact that in the solution used the concentration of the calcium phosphorus compound was near the point at which spontaneous precipitation might be expected to occur. In normal plasma, as already mentioned, calcium and phosphorus remain in solution at these concentrations because it contains protein which depresses the ionization of calcium; the ion product upon which precipitation depends is therefore considerably lower. Robison and Soames showed that calcium phosphate precipitates after a few days from a solution such as that employed by Shipley and associates if simply allowed to stand. It was found indeed by the latter workers that the addition of protein to the extent of 1 or 2 per cent, inhibited the calcification of the immersed bone. Robison and Soames showed later that though calcification of rachitic bone will occur when immersed in a solution containing calcium and phosphorus if the concentrations are sufficiently high, i.e., $\text{Ca} \times \text{P}$ product over 40 (4 mg. P and 10 mg. Ca per 100 cc.), calcification will not occur if the product is lower than this unless a phosphoric ester is added. Quite small amounts of the ester (glycerophosphate) were sufficient to cause calcification.

(d) Phosphatase is present in bone in largest amounts when and where active calcification is taking place (see

below) which strongly suggests that it plays an essential rôle in the calcification process.

(e) Certain facts have been cited as opposed to the phosphatase hypothesis: (a) in rickets the phosphatase activity of bone and plasma is increased rather than the reverse, and in the blood of rachitic rats the percentage of phosphoric esters hydrolyzable by phosphatase is not below normal. (b) Normal plasma contains only very small quantities of phosphoric ester which seem inadequate to supply the inorganic phosphate necessary for the calcification process. (c) Certain tissues which do not calcify normally are rich in phosphatase while other tissues such as the arteries which are frequently the site of pathological calcification, do not contain the enzyme.

Robison does not contend, however that the phosphatase mechanism is the only one concerned in the calcification process for, as mentioned above, calcification will occur in the absence of a phosphoric ester provided the concentrations of calcium and inorganic phosphate are sufficiently high. He and his colleagues found that when bone slices were treated with KCN or with certain fat solvents (alcohol, chloroform or acetone) before placing them in the supersaturated solution, calcification did not occur in the absence of glycerophosphate. These substances, however, exerted little or no inhibitory effect if glycerophosphate were present, i.e., the phosphatase mechanism was not paralyzed and calcification proceeded. Formalin, on the contrary, prevented calcification whether a phosphoric ester was present or not. These results, in Robison's view, point to two distinct mechanisms governing the calcification process. (a) The phosphatase mechanism, poisoned by formalin, which produces in the fluids bathing the cartilage cells a state of supersaturation in respect to bone salt. (b) A mechanism poisoned by several agents, especially cyanide, which is responsible for the deposition of bone salts from a supersaturated solution, whether this is the result of phosphatase action or is brought to the cartilage matrix from another source. The nature of the second mechanism is unknown. It may be due, Robison suggests, to a "slight increase in the pH of the matrix fluid brought about by some membranous equilibrium." Since this mechanism is inhibited or paralyzed by cyanide it is evidently dependent also upon the activity of living cells.

The distribution and properties of phosphatase

Phosphatase is present in greatest amounts in ossifying cartilage, in smaller amounts in forming bone, but is absent from resting epiphyseal cartilage and from non-ossifying cartilage in other situations. It was shown by Robison to be absent from the patella before the appearance of the ossification center in this bone but present thereafter. The teeth of young animals contain

in relatively large amounts. It is present in milk⁷ and also in the floral parts of plants.

The optimum pH for phosphatase activity is round 9.0. Magnesium greatly increases the activity of the enzyme, whereas calcium ions are mildly inhibitory. Phosphatase activity has been demonstrated in a number of tissues (see table 70).

casein; guanylic and adenylic acids of yeast nucleic acid; pyrophosphoric acid; and fructose phosphoric acid. Inosinic acid and pyrimidine nucleotides (p. 564) are hydrolyzed by intestinal and kidney phosphatase and also probably by bone phosphatase.

The significance of the presence of phosphatase in kidney, intestine and tissues other than bone is obscure. The pathological calcification of arteries such as the aorta, which Kay states does not con-

tain the enzyme, cannot be satisfactorily explained upon the phosphatase hypothesis.

The phosphatase in bone and the other solid tissues mentioned is reduced by the administration of irradiated ergosterol in amounts which cause the withdrawal of calcium from the bones and calcification of the tissues, whereas small doses cause an increase. On the other hand, it has been shown by Kay that the plasma phosphatase is increased, often markedly, in diseases involving extensive changes in bone structure (see table 71).

DEFECTS OF OSSIFICATION AND PATHOLOGICAL CALCIFICATIONS

Diseases of bone

Several of these have been considered in other parts of the text—*rickets* in Chapter LVI and on page 712; *osteomalacia* on page 656, *celiac rickets* on page 657, and *osteitis fibrosa cystica* on page 708.

The hardness, strength and rigidity of healthy bone depend upon the proportions of the organic and inorganic constituents incorporated into its structure, much as the properties of a plaster bandage depend upon the impregnation of the cotton mesh with plaster of Paris. The mineral and fibrous components are of equal importance; each reinforces the other. The cotton bandage has a certain tensile strength but lacks rigidity; a cast of plaster of Paris alone has maximum rigidity, but is brittle and readily broken or crushed. In most bone diseases the normal proportions between these two components are altered. In rickets and osteomalacia, for example, the bone salts are reduced in relation to the organic material. In these diseases, as also in osteitis fibrosa cystica, the bones are in consequence softer and more yielding than the normal. In certain other bone conditions the proportion of mineral to organic material is increased. The bone as a result is brittle and easily fractured. In other instances again there may be little change in the proportion of these two materials but the mass of the bone is increased or diminished with corresponding variations in strength.

Osteitis deformans (*Paget's disease*) is a disease of the skeleton involving mainly the bones of the skull, pelvis, limbs and spine. The cranium is enlarged and its wall greatly thickened, the long bones of the limb are massive and curved, the back is bowed (kyphosis) and its movements restricted. The organic matter of the bones is increased and the calcium content decreased, but

the total amount of phosphorus is not far from normal. A pronounced degree of arteriosclerosis is frequently a feature. Metabolic studies in the disease have yielded little information, though there is said to be a retention of calcium and phosphorus.

Fragilitas ossium (*osteogenesis imperfecta*) is a congenital disease characterized by thinness and extreme fragility of the skeleton, especially of the long bone and ribs. The cranium shows defective calcification. Fractures result from the most trivial injuries or may occur without any apparent cause. Union and healing of the fractures occur, however, as readily as in a normal bone. The bones have a low calcium content, the cortex is very thin and the medullary cavity dilated.

Achondroplasia is a congenital disease in which endochondral ossification (p. 713) of the limb bones especially the humeri and femora, is defective. Periosteal ossification is active. The long bones are therefore much shorter and thicker than normal, strong and dense. A characteristic type of dwarf results—short arms and legs with a trunk and head of almost normal dimensions. The bones of the base of the skull fuse prematurely and the development of certain facial bones is abnormal. Achondroplastic dwarfs develop as a result of these abnormalities a distinctive facies—depressed nasal bridge (pugnose), broad forehead and prominent lower jaw.

The cause or causes of the three foregoing osseous abnormalities is unknown. The possibility of some endocrine disorder, of course, comes to mind, but there is little or no evidence of such.

Marble or chalky bone (*Albers-Schönbergs disease*). In this condition the density of the bone is greatly increased; the cancellous tissue is filled with a chalky material and the medullary canal may be almost obliterated by the concentric thickening of the shaft. The excessive calcification, however, renders the bone soft and brittle. Calcification of soft tissues—arteries, lungs, tendons—is often a feature. The disease is exceedingly rare and is mentioned here only because of the interesting possibility that some abnormality of parathyroid function is responsible. A case has been reported by French observers in which there was enlargement of the parathyroids, and Selye has produced in rats a state of increased bone density, which he considers comparable to this disease, by the administration of parathyroid extract after the animals had become tolerant to the usual action of the hormone.

Renal rickets. This is a condition commencing most usually in childhood and associated with chronic nephritis, rarefaction of the skeleton, dwarfism, low serum calcium and sometime calcium deposits in the soft tissues and especially in the kidneys. The parathyroids usually show hyperplasia. We have seen that a rise in serum phosphate causes a reciprocal reduction in serum

calcium and it is generally held that the hypocalcemia seen in this disease is due to the retention of phosphate resulting from the renal insufficiency. The hypocalcemia so produced causes, it is presumed, a drain of calcium from the bones. Increased excretion of phosphate into the intestine is a result of the diminished excretion by the kidney, with consequent depression of calcium absorption (p. 711) is probably a contributory factor in the production of the low serum calcium. Albright and his colleagues suggest that renal osteitis fibrosa cystica (p. 708) is a more appropriate name for this disease than renal rickets inasmuch as the histological changes in the bones are indistinguishable from *primary* hyperparathyroidism. This brings up the question as to whether the demineralization of the skeleton is due to the hyperparathyroidism induced as a compensatory reaction to the low serum calcium, caused in turn by the phosphate retention, or whether the bone changes and parathyroid hyperplasia are independent results of the hypocalcemia. No definite answer can be given to this question. Obviously, since kidney disease not infrequently results from hyperparathyroidism (p. 708) and parathyroid hyperplasia may occur in chronic renal disease, it is very difficult if not impossible in a given case (especially if the subject is an adult) to decide whether the parathyroid abnormality is a primary or a secondary factor.

Calcification of soft tissues

DYSTROPHIC CALCIFICATION is the term applied to the deposition of calcium salts in dead, dying or chronically inflamed tissues and in areas of fatty or hyaline degeneration. Thus areas of necrosis, infarcts, scar tissue, caseous tuberculous areas and degenerated nerve cells, tend to undergo calcification. Calcification also occurs in the infarcts of the placenta which appear in the later half of pregnancy. Many of the examples of pathological calcifications to be described are simply special examples of dystrophic calcification. The factors determining the deposition of calcium salts in devitalized tissues are obscure. It has been suggested that since the CO_2 production in such tissue is minimal or entirely absent they will have a more alkaline reaction; this, of course, would tend to cause the deposition of calcium salts.

CALCINOSIS is the name given to conditions in which (a) calcified areas are scattered throughout the skin and subcutaneous tissues (*calcinosis circumscripta*), or (b) a more generalized calcification of skin, interstitial tis-

sues, tendons, fascia or muscles occurs (*calcinosis universalis*). When the calcification process involves predominantly the interstitial tissues of the muscles the condition is usually referred to as *myositis ossificans*. In calcinosis the calcium and phosphorus levels of the blood are normal. Metabolic studies have in some instances revealed a retention of calcium. In the region of the calcified areas true bone formation may occur. Calcinosis of the superficial tissues is in many cases associated with scleroderma (a condition characterized by induration of the skin due to an increase in the intercellular collagenous tissue). The cause of calcinosis is obscure; the calcification process may be secondary to degenerative changes in the tissues themselves. There is no evidence that it is dependent upon an abnormality of parathyroid function, though Selye has reported a condition in rats resembling scleroderma following the administration of parathyroid extract.

ARTERIAL CALCIFICATION. (1) *Arteriosclerosis* is seen in three main forms: (a) the *atherosclerosis* (atherē = crushed grain, porridge) of *Marchand*, (b) the *medial sclerosis of Mönckeberg*, and (c) *diffuse hyperplastic sclerosis* involving the arterioles. In the first two of these forms but not in the last, calcification plays a prominent rôle.

In *atherosclerosis* the aorta and its branches are the principal sites of the disease. The most noticeable changes occur in the intima, though degeneration of the elastic tissue, fibrosis and calcification of the media are also seen. The endothelial cells lining the vessel show hyperplasia, the thickened intima later undergoing hyaline or fatty degeneration; the fatty or atheromatous areas, which actually consist of deposits of cholesterol esters, finally become calcified. Calcareous plaques are thus formed upon the intima of the vascular wall. According to Klotz, calcium first combines with fatty acids in the degenerated area to form a calcium soap; the deposition of calcium phosphate and calcium carbonate occurs later. The pronounced tendency for calcification to occur in areas undergoing fatty change, e.g., in degenerating lipomata and in fat necrosis, support the conception that saponification precedes the deposition of lime salts. Objections have nevertheless been raised against the view that soap formation is a necessary preliminary, in all cases at any rate, to the calcification process. Wells states that calcium soaps cannot be extracted from arterial tissues undergoing fatty changes even very early in the degenerative process, but calcium phosphate and carbonate are present from the start. In addition, calcium soaps introduced into the tissues are removed and not transformed into calcium phosphate and carbonate.

It is believed by some observers following the theory of Thoma that the onset of the degenerative changes is secondary to deterioration of the elastic tissue of the intima and media, which by weakening the arterial wall permits distention of the vessel. The stretching interferes, it is presumed, with the blood supply of the vascular wall; the intimal thickening is looked upon as a compensatory process. Klotz, on the contrary, considered the intimal proliferation as a primary process due possibly to a toxic agent.

In medial sclerosis the degenerative changes are situated predominantly in the media of the vessels of the extremities. Degeneration of the elastic tissue and fibrosis of the smooth muscle occur, followed by calcification of the degenerated tissue. The vessels are converted into relatively rigid tubes—the so-called “pipe stem” arteries. The mineral tends to be laid down in rings encircling the vessel, which has suggested a comparison with the artery to a “goose’s trachea.”

The degeneration of the elastic tissues of the arteries which is such a prominent feature, and possibly the primary change, in both types of the disease is attributed to “wear and tear”—the repeated stretchings and recoils of the arterial wall—and to the inherent tendency for elastic tissue in general to deteriorate with age. Arteriosclerosis in one or other of the two types just described is, therefore, a disease of advancing years or is brought on prematurely by the excessive arterial strain caused by arterial hypertension (p. 135). The diffuse hyperplastic type (c) is, however, more characteristically a consequence of hypertension.

Arterial calcification may be looked upon simply as a particular type of dystrophic calcification and not specific in nature.

(2) *Arterial calcification associated with disturbances of calcium metabolism.* Calcium deposition in the arterial walls is often a pronounced feature of metastatic calcification; this is described in the next paragraph.

METASTATIC CALCIFICATION. This term implies a transference of calcium from the skeleton to the soft tissues. It occurs in animals treated with excessive doses of parathyroid extract or irradiated ergosterol. Though the calcium deposits may be found in any of the soft tissues, the arteries, kidneys and lungs are especially susceptible to calcification. The fundus of the stomach is also a common site. It will be noted that the three last-mentioned organs eliminate acid; and it has

been suggested that since this will leave the blood more alkaline in reaction, a condition favorable to calcium deposition is created. Metastatic calcification also occurs occasionally clinically. It has been reported in hyperparathyroidism (p. 708), renal rickets and in certain bone diseases e.g., multiple myelomata. It is very natural to assume that in conditions of disturbed calcium metabolism and destructive disease of bone the calcium deposits are simply the result of the excessive calcium in the circulation. It is quite possible, however, that, in some instances at any rate, it is secondary to tissue injury and may therefore be, in reality, a type of dystrophic calcification induced by a toxic agent. Parathyroid extract and irradiated ergosterol, for example, besides their effects upon calcium metabolism have a definitely toxic action. Furthermore, metastatic calcification is in some instances associated with hypocalcemia.

It is a fact of great interest that the calcium deposits in the arteries and in other soft tissues in the various types of pathological calcification have the same composition as the main mineral compounds of bone. Evidence obtained by both chemical and physical methods support this conclusion. In certain instances actual bone formation occurs, even to the extent of producing red marrow tissue. Areas of ossification have been observed in the aorta and in the neighborhood of calcium deposits in the necrotic kidney of the rabbit. Also, as shown by Huggins, if a section of the mucosa of the bladder be transplanted into the subcutaneous tissues it becomes the site of bone formation.

Renal calculi (nephrolithiasis, urolithiasis)

Kidney and bladder stones composed largely of calcium phosphate have been produced in experimental animals (rats) by the administration of irradiated ergosterol in excess. They are apparently the result of the excretion in the urine of large amounts of calcium liberated from the bone. Renal or vesical calculi are also associated with various bone diseases of a destructive nature; they are quite frequent in hyperparathyroidism. The great majority of renal calculi arise, however, unassociated with any other disease and a large proportion of them are composed of other materials than calcium phosphate (e.g., uric acid, urates, oxalates, cystine, etc.). Nephrolithiasis is particularly prevalent in the tropics and the

sibility has been suggested that hypervitaminosis D, due to over-irradiation with ultraviolet light and, possibly, deficiency of vitamin A are causative factors. The production of renal calculi in animals by hypervitaminosis D, as mentioned above, occurs only, however, when hormones are employed which cause bone resorption and an increased concentration of calcium in the urine. Such results have therefore little bearing

upon the question of the production of urinary calculi in the human subject. Also, though there is some evidence that avitaminosis A is conducive to the development of urinary calculi in animals (the cornification of the epithelium of the urinary tract being, apparently, a predisposing factor), there is little warrant for applying the results of animal experiments to the question of urinary lithiasis in man.

CHAPTER LXI

THE PITUITARY GLAND (HYPOPHYSIS CEREBRI)

DEVELOPMENT AND STRUCTURE

The average weight of the human hypophysis is about 0.5 gram. Its average dimensions are $10 \times 13 \times 6$ mm., it is larger in females, especially in those who have borne children, than in males. The gland is attached to the base of the brain between the optic chiasma in front and the tuber cinereum and corpora mammillaria behind by a short stalk. The gland proper is ensconced within the small cavity formed by the sella turcica of the sphenoid which is closed above by a membrane—the *diaphragma sellae*. The latter is pierced by the pituitary stalk. Upon gross examination the pituitary is seen to consist of two parts—the *anterior* and *posterior lobes*—which can be readily separated with the fingers. These parts differ from one another developmentally, histologically and functionally.

The *anterior lobe* arises as an evagination of the ectoderm of the primitive buccal cavity. This hollow pouch (craniopharyngeal duct or pouch of Rathke) grows upwards to meet the downgrowing evagination of the floor of the 3rd ventricle which is destined to form the *pars nervosa* of the *posterior lobe*. The pressure of the hollow anterior lobe rudiment against the developing *pars nervosa* causes invagination of the posterior wall of the former and the almost complete obliteration of its cavity. A narrow cleft alone persists in the fully formed gland to represent the collapsed cavity of Rathke's pouch. It is the presence of this cleft which allows the gland to be so easily separated into two parts. These two rudimentary parts of the pituitary are dependent upon one another for their subsequent development, as is shown by the fact that neither one when grafted into an animal will grow unless it is accompanied by a fragment of the other (Blount). Though the fully formed human posterior lobe and stalk are quite solid in some animals such as the cat the cavity persists to adult life and communicates with the 3rd ventricle.

That portion of the pituitary which is derived from the posterior wall of Rathke's pouch, and is in intimate contact with the posterior lobe, but separated from the bulk of the anterior lobe by the cleft, is known as the *pars intermedia*. In animals, the latter is only 2.5 per cent of the entire gland. The portion of the gland lying in front of the *pars intermedia* and separated from it by the cleft is called the *pars anterior*. The epithelial tissue originally derived from Rathke's pouch also extends upwards and spreads over the base of the brain around the pituitary stalk. This layer of tissue, since it invests the tuber cinereum, is called the

pars tuberalis; it is considered a part of the anterior lobe. The *pars intermedia*, though from its origin should be considered a part of the anterior lobe is, account of its close association with the posterior lobe, usually included as a part of the latter. The several parts of the pituitary are shown in figure 2 and listed in the subjoined table.

Origin	From primitive buccal cavity	<div> <div>pars anterior</div> <div>pars tuberalis</div> <div>pars intermedia</div> </div>	anterior lobe
	From floor of 3rd ventricle	<div> <div>pars nervosa</div> <div>pituitary stalk</div> </div>	posterior lobe

The *pars anterior* is richly vascular, showing numerous blood sinuses between cords of cells. The cells fall into two main groups, (1) *chromophobe* or *residual* cells which possess no granules, stain lightly and apparently do not secrete, (2) *chromophil* cells which contain large numbers of granules which stain readily. They are believed to elaborate the secretion of the anterior lobe. On a basis of the character of the granules, the chromophil cells are grouped again in two varieties, (a) *acidophil* (or *alpha*) cells which stain more readily with acid dyes, and (b) *basophil* (or *beta*) cells which have a greater affinity for basic stains. The three types of cell (chromophobe and the two types of chromophil cell) are scattered indiscriminately throughout the *pars anterior*. The proportions found by Rasmussen in man, were around 50 per cent chromophobes, 35 per cent acidophils and 15 per cent basophils. The last are increased after castration (p. 756). It now appears that the chromophobes represent an early stage in the development of the granular (chromophil) cells and give rise to either acidophils or basophils. The *pars intermedia* of man often shows cysts of various sizes containing a hyaline or colloid material and a few cells filled with the same material (*hyaline bodies*). The *pars tuberalis* resembles the *pars anterior* in being constituted of cords of cells separated by blood sinuses. The cells, however, are non-granular.

The *pars nervosa*, including the *stalk*, is composed (a) neuroglial cells, (b) fusiform cells with several processes and containing granules of a brown pigment in their cytoplasm (*pituitocytes*), (c) numerous nerve fibers, and (d) hyaline bodies. The hyaline bodies were believed by Herring, Cushing and others to represent cells of the *pars intermedia* and *pars tuberalis* which have undergone a hyaline change and are traveling the *pars nervosa* and stalk to reach the 3rd ventricle.

the hyaline material with which they are filled has been thought to represent the hormone of the posterior lobe. Some doubt has been thrown upon this view and many consider these bodies simply as artefacts.

Wislocki and King have investigated the blood supply of the hypophysis of the monkey and of man. The following description is based upon their observations. Except for a few capillary anastomoses, the blood supply of the pituitary is independent of that of the brain proper. It is derived from the hypophyseal arteries, branches of the internal carotid. The circulation of the pars anterior and pituitary stalk is also separate from that of the pars nervosa. The stalk receives its blood supply from the superior hypophyseal arteries which form a rich plexus surrounding it and covering the pars tuberalis. Blood from the stalk drains into venules tributary to the plexus. As pointed out a few years ago by Popa and Fielding the general plan of the circulation of the pars anterior resembles that of the liver. Portal venules arising from the

FIG. 284. Hypophysis of cat. 1, pars anterior; 2, hypophysial cleft; 3, pars intermedia; 4, pars nervosa; 5, infundibular cavity; 6, pars tuberalis, and 7, optic chiasm. (From Cowdray, redrawn after Herring.)

plexus surrounding the pituitary stalk terminate in the sinusoids of the pars anterior. The sinusoids receive blood as well from branches of the superior hypophyseal arteries, and drain into the cavernous sinus. The blood supply of the pars nervosa is derived from the inferior hypophyseal arteries.

THE NERVE FIBER CONNECTIONS OF THE HYPOPHYSIS. The pituitary is supplied with fibers derived from the internal carotid nerve plexus. The cell stations of these fibers are in the superior cervical ganglion; they reach the gland along blood vessels which descend the pituitary stalk. The *posterior lobe* also receives fibers (50,000 in number according to one estimate) from the supra-optic nucleus and tuber cinereum situated in the hypothalamus. From the hypothalamic nuclei a few fibers have been traced into the pars intermedia and fewer still for a short distance into the pars anterior. (See fig. 374, p. 1486.) The secretory activity of the pituitary can be aroused by stimulation of the cervical sympathetic.

THE PHYSIOLOGY OF THE PITUITARY

THE ANTERIOR LOBE

The anterior lobe of the pituitary is the master gland of the endocrine system. At least eleven types of physiological effect have been identified with this part of the pituitary. Six of these, since they can be produced each by an extract relatively free from other effects, are generally attributed to distinct and separate hormones, namely, (1) the *growth* hormone, (2) the *thyrotropic* (or *thyrotrophic*)¹ hormone, (3) the *adrenocorticotrophic* (or *adrenocorticotrophic*) hormone, (4) and (5) the *gonadotropic* (or *gonadotrophic*) hormones, and (6) *prolactin* or the *lactogenic* hormone.

The remaining effects of anterior lobe extracts, but for which separate hormones have not been definitely demonstrated, are: (7) *ketogenic*, (8) *insulin antagonizing* or *glycotropic*, (9) *diabetogenic*, (10) *parathyrotrophic* and (11) *pancreatrophic*. These various actions of anterior pituitary extracts can be divided into two main groups; (a) those such as the effects upon growth, milk secretion, fat metabolism, etc., which are exerted upon peripheral tissues, and (b) those which act upon other endocrines, e.g., thyroid, adrenal cortex, gonads, etc.; these latter are given names composed in each instance of the name of the gland acted upon and the suffix *tropic*.

Though convenient and customary, it is scarcely correct to speak of these pituitary principles as hormones, for there are no means of knowing whether or not the active materials obtained by extraction of the dead pituitary, often by rather drastic methods, are secreted by the living gland. There are only three characteristic types of cell in the anterior lobe of the pituitary and the evidence points to only two—the acidophils and basophils—as elaborating physiologically active principles. It is hardly credible that the several extraction products of the anterior lobe represent true hormones secreted by these two cell types. In other words, as Riddle says, too many hormones have been

¹ The Third International Conference on the Standardization of Hormones has recommended that the suffix *-tropic* in the adjectives qualifying the hormones of the anterior pituitary be replaced by *-trophic* (See Collip), and that the termination *-trophin* be used in forming the name of the hormone (e.g. thyrotrophin for the thyrotropic hormone). The suffix *-tropic* is from the Greek *τρέπειν*, to turn, and in this sense has been used in such terms as heliotropic, geotropic etc. The suffix *-trophic* is derived from the Greek word *τροφή*, to nourish or nurture and is, therefore, more appropriate as an ending for those pituitary hormones which affect the development and growth of other endocrines.

postulated. He suggests that at the most there are probably but two true hormones, one with lactogenic, adrenotropic and growth effects secreted by the acidophil cells, and another with gonadotropic and possibly thyrotropic effects secreted by the basophils. The different products which have been obtained in nearly pure form, as judged by the predominant physiological effects which they exert, he prefers to call "hormone fragments." Collip also visualises two large hormone molecules with prosthetic groups possessing the specific physiological actions demonstrable in the various laboratory products and which represent, presumably, parts broken off or "chemically dissected" from one or other of the parent compounds. Of the principles which have been obtained from pituitary tissue only the lactogenic, follicle-stimulating and possibly the luteinizing (p. 756) have been demonstrated in the blood. Until this has been done for any particular pituitary extract it is not justifiable to conclude that it is secreted as such by the gland. The pituitary principles are protein in nature, but none has been synthesized nor has any been isolated in crystalline form, with the exception of prolactin (p. 765). Little is known of their chemical structure, although from certain investigations, it appears that the gonadotropic principles are glycoproteins containing glycosamine and a hexose which is probably mannose. It has been rather surprising to find, that unlike the thyroid hormone, insulin etc., the pituitary principles are species specific. Thus, differences in action have been shown between the pituitary hormones of sheep, pigs and cattle.

The effects of hypophysectomy are for the most part attributable to the withdrawal of the actions of the anterior lobe secretion upon various physiological functions. In competent hands complete ablation of the pituitary is not the fatal operation it was once believed to be; animals survive for long periods during which they can be studied, though undoubtedly their life span is shortened as a result of the abnormalities which result. Among the chief effects of hypophysectomy are (1) arrested growth, (2) atrophy of the gonads and, indirectly, of the accessory organs of sex, (3) suppression of milk secretion and involution of the mammary glands, (4) atrophy of the thyroid and adrenal cortex and probably degenerative changes in the parathyroids, (5) lowered metabolic rate, (6) hypoglycemia and increased sensitivity to insulin, reduction in liver and muscle glycogen, (7) depression of spontaneous activity, (8) diminished resistance to infections and shock.

The growth hormone

It has been known for many years as a result of the study of growth abnormalities in man

(acromegaly, gigantism and dwarfism) that the anterior lobe of the hypophysis influences skeletal growth. Experimental work also indicated such a function, removal of the posterior lobe and part of the anterior from puppies resulting in dwarfing, sexual infantilism and obesity (Aschner, Cushing). Removal of the anterior lobe in tadpoles was shown by Smith and by All to result in retarded growth, failure of metamorphosis and a reduction in pigmentation of the body surface. The final proof that the anterior lobe secreted a growth-promoting hormone was furnished by the experiments of Evans and Long

FIG. 285. Curve of average growth of 38 female rats which were treated daily with intraperitoneal injection of anterior lobe extract, and that of 38 littermate sister controls (untreated). (After Evans.)

who found that a saline or alkaline extract of the gland when given daily to rats by intraperitoneal injection (but not by mouth) extended the growth period beyond the normal limit. Some of these animals finally attained a size larger by 10 per cent or more than that of their untreated littermates (see fig. 285). The effect was usually greater in females. Similar results have been obtained in dogs. Gigantism, acromegaly and splanchnomegaly (p. 737) have been produced in bulldogs by Putnam, Benedict and Teel. Air dales, Boston terriers and dachshunds have been shown by others to respond to such an extract (see fig. 286). Potent extracts free from gonadotropic and containing only traces of thyrotropic, adrenotropic and lactogenic principles have been

prepared.² As might be expected, the stimulus to growth is accompanied by a retention of nitrogen. An increase in deposit protein appears to be one of the first changes in protein metabolism caused by the growth principle. There is no appreciable change, however, in the calcium balance. The growth principle is almost certainly elaborated by the acidophil cells. The pituitaries of dwarf mice are lacking in acidophils while acromegaly and gigantism are frequently associated with tumors composed of these elements.

It might with reason be asked, "Does the growth principle act indirectly by stimulating other glands which are known to be influenced by the pituitary, e.g., the thyroid, adrenals or gonads?" Such an indirect mode of action is disproved by the fact that growth cannot be induced in an hypophysectomized animal by the administration of an extract of any of these glands. On the other hand, growth can be induced in hypophysectomized animals or stimulated in young normal animals by means of pituitary extracts containing only traces of "tropic" principles. The growth hormone should not, however, be looked upon as the

FIG. 286. Litter mate female dachshunds 11½ months old. HY-26 injected with growth hormone for 35 weeks HY-27 control. (After Evans and associates.)

Diabetogenic and ketogenic effects are associated with the growth hormone and cannot be completely separated from it. The growth hormone exhibits other metabolic effects, namely, depression of the respiratory quotient, a decrease in arginase of the liver and of insulin in the pancreas. Also, the specific dynamic action of protein appears to be dependent upon this principle. It is not known whether these various metabolic effects are essentially and specifically related to the growth hormone or are due to separate and distinct principles.

The effect of hypophysectomy upon the growth of puppies is shown in fig. 287. The potency of a given anterior lobe extract in growth-promoting properties may be assayed by injecting it in measured amounts into rats whose growth has been completely arrested by subjecting them to hypophysectomy at the age of 100 days and thereafter following their growth curves. Normal rats are much less reactive to the hormone than the operated animals.

The pituitary of a full-grown animal contains as much growth hormone as those of young animals, but the rôle which it plays in the adult body is unknown. It may be mentioned, however, as an isolated observation that under its influence the growth of hair over a shaved part is more rapid than usual.

² Riddle and his associates doubt that a specific growth hormone exists; they believe that the growth effect is the result of the combined actions of prolactin and thyrotropin.

FIG. 287. Hypophysectomized puppy (right) and litter-mate control (left) three months after removal of the hypophysis when three weeks old. (After Dandy and Rickert.)

supreme factor controlling growth in the sense that cell multiplication and the growth of tissues and organs are arrested when it is withdrawn. That the growth of individual organs is not abolished is shown by the facts that in the absence of the pituitary mitotic figures appear in the mammary glands of parturient rats, and, hypertrophy of the remaining kidney follows unilateral nephrectomy. The pituitary appears to preside over the growth of the body as a whole and to control the proportional growth of the several organs and parts.

The thyrotropic (or thyrotrophic) hormone— thyrotropin (or thyrotrophin)

Hypophysectomy causes atrophy of the thyroid.³ On the other hand, an acid extract of the anterior

³ The thyroid exerts in turn an influence upon the pituitary as indicated by the fact that thyroidectomy is followed by hypertrophy of the pars anterior with degeneration of the basophil cells and disappearance

lobe of the pituitary has been prepared (Loeb and Bassett; Aron) which, when injected into animals, stimulates the thyroid. A homogeneous substance with a high thyrotropic activity, and which appears to be a pure protein (a pseudoglobulin), has been isolated more recently from beef pituitary tissue. It is free from growth and gonad-stimulating properties. Striking changes in the histological appearance of the thyroid result from the injection of thyrotropin; the colloid material disappears, the epithelium becomes hyperplastic and the alveolar cavities collapse (fig. 288). Mitotic figures (especially after the administration of colchicine (p. 766) appear in the thyroid in large numbers; whereas in the normal gland of the guinea-pig about 150 mitoses can be found, nearly 200,000 may appear after the administration of a potent thyrotropic principle. Signs of hyperthyroidism, e.g., increase in heart rate, rise in metabolic rate, increased susceptibility to oxygen want and increased tolerance to acetonitrile have been observed by various workers. It decreases the iodine content of the gland in normal animals while raising that of the blood. The iodine intake exerts an important effect upon the action of the hormone, a fact which has an important bearing upon the mode of action of iodine in the treatment of Graves' disease. It was found by Anderson and Evans in experiments on rats that at certain levels of dietary iodine the thyrotropic principle, while it induced thyroid hyperplasia in the usual way, did not raise the metabolic rate. In other words, iodine appears to prevent the release of the thyroid hormone without preventing the action of the thyrotropic principle from exerting its usual effect upon the thyroid cells.

Thyrotropin has been demonstrated in normal blood and urine. Its concentration in the blood is increased in acromegaly and hyperthyroidism, but reduced in Simmond's disease (see also p. 738).

The thyrotropic hormone induces creatinuria and increased calcium excretion, and a reduction of liver glycogen in ordinary laboratory animals, and hastens the metamorphosis of tadpoles—all well known thyroid effects. None of the effects so far listed can be produced after removal of the thyroid.

of the acidophils. The administration of thyroxine causes a reduction in number of the granules in the acidophil cells. According to Evans the growth-promoting function of the pituitary is dependent upon a normally functioning thyroid. He states that thyroidless tadpoles can be induced to metamorphose or cretin dwarfs to grow by either the administration of thyroid, which stimulates the hypophysis, or by treatment with the pituitary growth hormone itself.

Thyrotropin causes exophthalmos in the guinea-pig, either in the normal or thyroidectomized animal (p. 677) and prevents atrophy of thyroid in hypophysectomized rats. Its action has been demonstrated in man, injections causing a rise in the metabolic rate in normal persons, hyperthyroid patients and those suffering from pituitary deficiency, but not in subjects of hypothyroidism. *In vitro*, this hormone causes hyperplasia of sliced thyroid tissue, evidence that its action is directly upon the thyroid cells. A pure thyrotropic hormone has been obtained free from the growth and gonad-stimulating principles, not free from traces of the adrenotropic principle. The normal rat, after an initial response period during which hyperplasia of the thyroid and a rise in metabolic rate occur, becomes refractory to thyrotropic hormone. The refractoriness has been shown by Collip and Anderson to be due to the formation of an inhibiting substance (a hormone (see p. 729)) which they have found in the serum of the treated animals. Friedgood has found that though guinea pigs responded at first to anterior pituitary extract by thyroid hyperplasia and a rise in the basal metabolic rate, the animals later became refractory. The responsive period was followed by one during which the B.M.R. returned to normal or to a subnormal level (though injections were continued); the thyroid hyperplasia, however, persisted. Eventually the thyroid returned to its normal size and histological appearance, in spite of the uninterrupted administration of the extract. Slight prominence of eyeballs appeared toward the end of the responsive phase, but the most pronounced exophthalmos occurred during the refractory phase. The production of the effect upon the eyes appears therefore, to be independent of the effect upon B.M.R. It has been mentioned elsewhere that exophthalmos has been induced by administration of anterior pituitary extract in thyroidectomized animals.

The discovery of the thyrotropic hormone and the observations just cited suggest at once the possibility that exophthalmic goiter and certain instances of hypothyroidism are primarily of pituitary origin—excess and deficiency, respectively, of the thyrotropic principle.

The adrenocorticotrophic (or adrenocorticotrophic) hormone—corticotropin (or corticotrophin)

Hypophysectomy in the rat leads to atrophy of the cortex of the adrenal (fig. 289). Hypertrophy of the adrenals (cortex and medulla) is

erved by Cushing and Davidoff in hyperactivity of the anterior pituitary in man (see hypomegaly and pituitary basophilism, p. 737); whereas pituitary cachexia (p. 738) is associated with adrenal atrophy. Adenomatous tumors of the adrenal cortex have been produced by the injection of anterior pituitary extracts into normal animals. Some cases of Addison's disease, it has been suggested, may be due to a pituitary defect, that is, to a deficiency of corticotropin; improvement of patients with this disease has been reported to follow the administration of the adrenocorticotrophic principle.

Collip and his colleagues (1933) were the first to prepare from the anterior pituitary an extract which acted specifically upon the adrenal cortex; it contained minimal amounts of other pituitary principles. This extract was highly effective in restoring to normal the atrophied adrenal cortex of

the production of those cortical principles possessing an oxygen atom at C_{11} . The production of those hormones lacking an oxygen atom at C_{11} does not appear to be stimulated by this pituitary principle.

The basophil cells are probably the source of corticotropin. A great reduction in the number of these cells is said to occur in some cases of Addison's disease.

The gonadotropic hormones and prolactin are dealt with in Chapter LXII.

The ketogenic effect

If an extract of the anterior lobe be injected into fasting rats, or rats receiving a diet of butter fat, a rise in acetone bodies in the urine and in the blood occurs (Burn and Ling, Anselmino and Hoffmann). The effect is not mediated through the thyroid for it is obtained in thyroidectomized

FIG. 288. The thyrotrophic hormone. Section of thyroid from normal guinea-pig on the left, that of litter mate treated with 8 mg. of anterior lobe substance on right. (After Van Dyke, *The physiology and pharmacology of the pituitary body*, Chicago University Press.)

hypophysectomized animals. A pure protein with high corticotropic activity was isolated by Li and associates in 1942, and by Sayers and his colleagues in 1943. The material obtained by the latter observers is free from thyrotropic and ketogenic actions. Its isoelectric point is at a pH between 4.7 and 4.8 and its molecular weight is around 20,000. It has a definite corticotropic action in daily doses of micrograms.

Corticotropin induces changes in the quantity and distribution of the doubly refracting (birefringent) lipid material in the cortical cells. Moderate doses cause a reduction of the fine granular particles. With larger doses the lipid is increased in the zona glomerulosa and zona fascicularis and appears in the form of larger accumulations which, it is suggested by some observers, represent the cortical hormone or its precursor in the storage phase (p. 684). Gratten and Jensen found that corticotropin stimulated

animals. It was thought, however, to be dependent upon the adrenal cortex since adrenalectomized animals treated with a potent ketogenic extract do not show ketonuria (Fry), whereas removal of the adrenal medulla alone does not prevent the response. It has been found, however, that the effect of the adrenal cortex is only upon the excretion of ketone bodies; adrenalectomy does not prevent their rising in the blood. Ketogenic extracts also cause an increased deposition of fat in the liver and a diminution of body fat, indicating the transference of fat from the latter to the former site, which suggests in turn that the ketosis is the result of the stimulation of fat catabolism, and the production of ketones beyond the capacity of the body to oxidize them. The ketogenic effect is closely associated with the growth hormone and the diabetogenic factor (see below). Animals develop a resistance to the action of ketogenic extracts after they have

received a number of injections (see *antihormones*, p. 729).

The insulin-antagonizing (glycotropic or glycotrophic) and diabetogenic factors
(see also p. 589)

Many observations associate the anterior lobe of the pituitary with carbohydrate metabolism. (a) Hyperglycemia, glycosuria, lowered sugar tolerance, are among the effects of overactivity of the anterior lobe in man (see acromegaly, p. 736). All the symptoms of a true diabetes mellitus may be present in this condition. (b) Evans and others observed the dachshund pups given daily injections of anterior lobe extract as

FIG. 289. Showing adrenal atrophy following hypophysectomy. Normal gland on left, gland of hypophysectomized animal on right. (After P. Smith.)

well as increasing 100 per cent in weight, exhibited great thirst, polyuria and glycosuria, and had a fasting blood sugar of 232 mg. per 100 cc. (normal 100 mg. per cent). (c) Hypophysectomy renders an animal hypersensitive to insulin and resistant to the hyperglycemic action of adrenaline, while implantations of anterior lobe or injections of an anterior lobe extract reduces the hypoglycemic action of the pancreatic hormone. It was also shown by Houssay that the diabetic symptoms following pancreatectomy almost disappear after hypophysectomy, but return when anterior lobe tissue is transplanted into the depancreatized and hypophysectomized animal. A pancreatectomized and hypophysectomized dog (Houssay dog) will live for several months without the aid of insulin;

during fasting the blood sugar is within normal limits, or there may be hypoglycemia; ketonuria is absent and the glycogen content of the liver is near the normal value. Houssay and Best conclude that the anterior lobe is concerned in the production of sugar from endogenous sources (see also p. 544). Corkill, Marks and Best suggested that the glycogen reserves of the liver are less readily mobilized after hypophysectomy and that this is a contributory factor in the hypersensitiveness to insulin of animals subjected to this operation. The hyperglycemic effect of anterior lobe extracts is not brought about through the adrenal since it occurs after adrenalectomy (Houssay).

In 1937 Young reported the extremely important finding that dogs given a series of daily injections of a crude extract of the anterior lobe became *permanently* diabetic (hyperglycemia, glycosuria and ketonuria), i.e., the diabetogenic effect continued after the administration of the extract was stopped, and persisted indefinitely. The pancreases of such animals show complete degeneration of the islets of Langerhans (Richardson and Young) and give an extremely low insulin response (Best and Campbell). These changes probably represent an "exhaustion atrophy" which accounts for the permanent diabetic state induced by the extract. The diabetogenic factor should not be confused with the insulin-antagonizing principle, or, as Young calls it, the glycotropic factor. The latter exerts a true anti-insulin effect. Experiments have been secured, for example, which, by reducing or preventing the hypoglycemic action of injected insulin, do not raise the blood sugar when administered alone. The glycotropic factor, which is distinct from the thyrotropic and gonadotropic principles and probably from the lactogenic factor, also inhibits the actions of insulin in accelerating the fall in blood sugar in hepatectomized animals (Himsworth and Scott) and in preventing the deposition of muscle glycogen (Marshall).

The parathyrotropic (or parathyrotrophic) factor

There is a considerable body of evidence which suggests that the anterior lobe exerts a controlling influence upon parathyroid function. The occurrence in the human subject of parathyroid adenomas with pituitary tumors has been reported. Decalcification of the skeleton occurs in pituitary basophilism (p. 737), though in a case of this disease Cushing found degeneration rather than hyperplasia of parathyroid tissue. Atrophy of the parathyroids has been reported in dogs

y and associates) and in rats (Smith) following hypophysectomy. Collip and his colleagues observed hypocalcemia and degenerative changes in the parathyroids in dogs after the removal of the pancreas and the hypophysis. Removal of the pituitary alone, however, does not lower the serum calcium, though a rise in serum calcium has been observed to result from injections of anterior pituitary extracts. Anselmino and Hoffmann claim to have produced parathyroid hyperplasia, often accompanied by hypercalcemia, by the injection of an anterior lobe extract into animals, and to postulate the existence of a specific parathyrotropic hormone. Similar results have been reported by Hertz and Kranes. Finally, Hertz and Albright have reported that the urine of a subject in whom there was a general hyperplasia of parathyroid tissue (hyperparathyroidism, p. 708), when injected into rabbits caused hyperplasia of their parathyroids. Although these several observations suggest some relationship between the pituitary and parathyroid function, there is no conclusive evidence that a specific parathyrotropic hormone exists; and that such a hormone is essential for parathyroid function is disproved by the fact that calcium metabolism, even in young animals, appears to suffer no impairment after hypophysectomy.

The pancreatic (or pancreatrophic) effect

Anselmino and Hoffmann reported the preparation of an anterior lobe extract which caused enlargement and an increase in the number of the islets of Langerhans together with a fall in blood sugar. The extract was free from thyrotropic effects. Their results, they believed, indicated the presence of a pancreatic hormone which stimulated insulin production. Richardson and Young have furnished confirmatory evidence of a pancreatic effect. They observed a 100 per cent increase in the quantity of islet tissue in the pancreases of rats receiving daily injections of a crude anterior lobe extract; many mitotic figures were seen in the islet cells of dogs treated with the extract. Marks and Young found that in rats the administration of a pituitary extract increased the insulin content of the pancreas. Ham and Haist have obtained histological evidence of a stimulating effect of a pituitary extract upon the islet and acinar tissue. After a few daily injections mitotic figures appeared in the beta cells of the islets as well as in the acinar cells. Signs of increased activity were also observed in the thyroid and adrenal cortex. The daily adminis-

tration of extract over a longer period led to degranulation followed by hydropic degeneration of the beta cells and, eventually, atrophy of the insulin-secreting tissue.

The pancreatic effects of pituitary extracts which have been just cited do not permit one to conclude that a specific pancreatotrophic hormone exists. Such effects more probably are brought about indirectly through the action of the diabetogenic or of the glycotrophic factor, that is, by increasing the demand for insulin. The fact that hypophysectomy is not followed by atrophy of the islets of Langerhans speaks very strongly against the effects being truly "tropic" in character.

ANTIHORMONES

Collip and his colleagues have demonstrated that certain hormones when injected cause the formation of a substance in the serum of the treated animal which exerts a specific antagonism to, and may completely abolish the effect of, the injected hormone. They claimed that the inhibitory principle was not an antibody in the ordinary sense, i.e., an immune body developed to some constituent of the hormone acting as antigen, but was rather in the nature of an *antihormone*. A substance of this character was first obtained by Collip and Anderson in 1934 in the course of experiments with the thyrotropic principle of the anterior pituitary. Rats after repeated injections of the thyrotropic hormone became refractory (p. 726), subsequently failing to respond to large doses. They were still responsive, however, to the thyroid hormone. It was found that the serum of these refractory animals was capable of preventing the effect of the thyrotropic hormone upon non-refractory animals. There is also evidence that the pituitary produces a substance (possibly paraxanthine) which antagonizes the thyroid hormone itself; an extract of the hypophyses of rats fed desiccated thyroid tissue reduces the metabolic rate of normal animals.⁴ To give another example of this antagonism: hypophysectomized rats treated with purified growth hormone fail to respond to it after a period of five or six weeks. The serum of such animals

⁴ Paraxanthine (1:7-dimethylxanthine) is an antithyroid substance which has been isolated by Carter and his associates from animal tissues and from human urine. In suitable dosage it antagonizes the action of thyroxine, lowering the metabolic rate and slowing the isolated frog heart. It is suggested that its presence in the body may be of physiological significance, the level of the metabolic rate being due not to thyroid action alone but also dependent upon the balance between it and the action of paraxanthine.

neutralizes the effect of the growth hormone upon other untreated hypophysectomized rats. Besides anti-thyrotropic and anti-growth principles, inhibitory substances have been shown to exist for the ketogenic, lactogenic and gonadotropic principles of the anterior pituitary, respectively, as well as for the anterior-pituitary-like principle (A.P.L.), but not for the adrenotropic, or parathyrotropic principles, or for insulin, or the sex hormones.

Collip suggested that the inhibitory principles or antihormones were present in the blood of normal animals, each serving to "oppose" or "buffer" the action of the corresponding hormone and that a given endocrine effect occurring naturally in the body was dependent upon the ratio existing between the hormone and antihormone concentrations. Disordered endocrine function whether in the direction of hyper- or hypoactivity might be, according to this conception, the result of an imbalance between the two antagonistic principles, rather than of an abnormal concentration of the hormonal principle alone. In other words, an endocrine deficiency might be due to too little of the hormone or to an excess of its antihormone; a hyper-endocrine state would be the result of a reverse relationship between these two principles.

Collip's observations have been confirmed repeatedly by other experimenters, so that the production of substances antagonistic to certain pituitary principles is a phenomenon established beyond all doubt. But there is a difference of opinion as to the nature of the inhibitory substances. The problem is one of extraordinary complexity for experimental investigation. Various workers have tried to answer the question whether the effect is due to antibodies, in the immunological sense of the term, produced by a foreign protein (antigen) closely associated with the active (hormone) principle, or to a substance—a true antihormone—which directly opposes the physiological action of the particular hormone itself. The demonstration that the effect was species specific would establish it as being in the nature of an antibody reaction. Evidence on this point, however, is conflicting. Collip found, for example, that a gonadotropic extract of sheep's pituitaries when injected into lambs caused the production in their sera of an antigonadotropic substance which antagonized gonadotropic extracts prepared from the pituitaries of hogs and cattle. The antigonadotropic serum when injected into rats inhibited the gonadotropic activity of their own pituitaries. These experiments afford strong evidence against the hormone inhibitor being an antibody. Rowlands and Parkes found also that a gonadotropic extract from ox pituitaries, upon injection into rabbits, caused the formation in their sera of a substance which protected other rabbits from the gonadotropic action, not only of the original (antigenic)

extract, but of extracts from sheep and horse pituitaries. Furthermore, the antigonadotropic serum given rabbits immediately after mating inhibited ovulation which normally would have occurred about 10 hours later (p. 756). In other words, the antagonist developed against ox gonadotropic principle inhibited the gonadotropic (ovulation) principle of the recipient animal's own pituitary. Also, the transplantation of rat's pituitary tissue into rats results in the production of inhibiting substances, in this instance there can be no question of a foreign protein exerting an antigenic effect. Finally, an antithyrotropic substance has been found in the blood of normal animals (dog, sheep, rabbit and man). On the other hand, in parabiosis experiments (p. 757), in which a hypophysectomized female rat is joined to a castrate, the gonads of the former are subjected to continuous stimulation by the pituitary of the latter; that is, a substance inhibitory to the gonadotropic principle of the pituitary is not produced under these circumstances. The substances are associated with the globulin fraction of the serum, a fact which argues for their belonging to the group of immune bodies. Their source is definitely known, but at any rate the antithyrotropic substance is not formed in the thyroid, for when thyrotropic hormone is added to fluid perfusing a surviving thyroid gland, there is no indication of formation of an antagonizing substance. Nor are they produced by the pituitary itself, for the effect is actually greater in hypophysectomized than in normal animals. There is some evidence that the spleen and other parts of the reticulo-endothelial system are concerned in their production. If this can be established it will be another point in favor of these substances being antibodies. In summary, it may be stated that the evidence perhaps weighs against the antihormone theory, but it would be unwise to form a definite opinion upon this perplexing question. It may be added, however, that the failure to find an answer has not been due to any lack of experimental ardor or ingenuity.

THE POSTERIOR LOBE

An active extract of the pituitary was first obtained in 1894 by Oliver and Schafer; its effect in raising the blood pressure was described. However, three years later showed that the posterior lobe alone contained the pressor principle. This extract has been used in medicine for several years under such commercial names as *Pituitrin*, *Infundin*, etc. or as a solution of the *Standard Pituitary powder* of the U.S.P. Much of our knowledge concerning the pharmacological and physiological actions of the principle of the posterior lobe has been gained from experiments with this relatively crude material and although it has been largely displaced by the more purified fractions *pit-*

and *pitocin* (p. 733) an account of its actions will first be given.

The Actions of a Solution of Standard Pituitary Powder or of a Commercial Pituitary Extract

These fall into 5 main groups.

(1) **CIRCULATORY.** The blood pressure is raised, the systemic arterioles and capillaries both undergoing constriction. Marked pallor of the skin results. An initial depressor effect, or a pressor succeeded by a depressor effect may precede the main rise in blood pressure. A second injection of the extract shortly after the first usually causes a depression of the blood pressure (*inversion effect*). Pituitrin causes constriction of the coronary and pulmonary vessels but dilates the cerebral and renal vessels. The dilator effect upon the two last mentioned sets of vessels is a passive one being caused by the rise in systemic blood pressure. The heart is slowed by pituitrin if the vagus nerves are intact, the effect being a reflex result of the blood pressure rise, but increased cardiac rate occurs if the nerves have first been cut. Some dilatation of the heart and weakening of its beat occur in the dog, rabbit and, with large doses, in the cat. The coronary constriction and the weakening effect upon the cardiac muscle cause a reduced cardiac output and a fall in pressure in the pulmonary artery (dog and rabbit). These experimental results indicate that commercial pituitrin is of no value *clinically* as a means of strengthening the action of a failing heart but may actually exert a deleterious effect. The fall in blood pressure which follows repeated injections of pituitrin (*inversion effect*) is due, according to Melville and Stehl, to the weakening of the heart and not of vascular origin. The portal venous pressure is reduced by pituitrin—as a result of constriction of the splanchnic vessels.

(2) **PLAIN MUSCLE** is stimulated by pituitrin. This action differs from the smooth muscle stimulating action of adrenaline in that it does not parallel the action of the sympathetic nerves; smooth muscle, receiving motor innervation from the parasympathetic, is excited as well. The muscular walls of the *uterus* (*oxytotic effect*), *intestine*, *gall-bladder*, *ureter* and *urinary bladder* (detrusor and trigone) are excited. Sometimes the smooth muscle of the bronchioles is stimulated, but this is due to contamination of the extract with histamine and is not specific. The stimulating effect of pituitrin upon the isolated virgin guinea-pig's uterus was demonstrated by Dale in 1909; it is used as a means of assaying the potency

of pituitary extracts. Some highly purified preparations exert an oxytotic effect in a dilution of 1 part in 2,000,000,000. The effect of pituitrin upon the uterine muscle is antagonized by the hormone of the corpus luteum (see p. 750). The oxytotic effect varies with the species, and, as a consequence of the interplay of other hormones, especially of the luteal hormone, with the phases of the sexual cycle (e.g., period of oestrus, pregnant or non-pregnant state of the uterus). An interrelation between the actions of adrenaline and pituitrin is indicated by the fact that if the non-pregnant uterus of the cat is first treated with pituitrin, adrenaline causes contraction instead of the usual relaxation (p. 687). The human uterus is most sensitive to the extract at the end of pregnancy, and pituitrin is used as an obstetric aid to induce uterine contraction after the expulsion of the placenta and so to prevent or check post-partum hemorrhage. The posterior pituitary principle also causes a temporary increase in the secretion of milk in lactating animals (so-called *galactagogue action*). This is not, however, a specific secretory effect but is due simply to the stimulation of smooth muscle in the walls of the mammary alveoli and ducts, and the expression of pre-formed milk (p. 768).

(3) **ANTIDIURETIC EFFECT.** This was discovered by Magnus and Schafer in 1901. In the conscious animal the injection of pituitrin may cause a very brief increase in the urinary flow due to the rise in general blood pressure and the passive dilatation, thereby, of the renal vessels. The important and specific renal effect is, however, an increase in the reabsorption of water and, as a consequence, a reduction in the urinary flow. In anesthetized animals the specific antidiuretic action is absent; diuresis due to the vascular factors is the outstanding effect. Pituitrin postpones for several hours the diuresis induced in normal animals by water drinking, and reduces the polyuria of diabetes insipidus. Associated with the antidiuretic effect is an increase in the percentage of chloride in the urine and, as a result of a reduction in the tubular reabsorption of chloride, an increase in the total amount excreted (pp. 385, 386 and 398). The antidiuretic principle is an essential factor in the maintenance of the water balance of the body, being secreted when the need for water conservation arises. For example, the quantity of the hormone in the urine, which reflects presumably its concentration in the blood stream, is increased in dehydrated states but decreased in hydremia (Gilman and Goodman).

(4) **METABOLIC EFFECTS.** Reduced tolerance for sugar, diminution in hepatic glycogen, hyperglycemia, glycosuria and a fall in the basal metabolic rate follow the injection of pituitrin. The effect of insulin is antagonized. That is, to say, the pancreatic hormone produces less effect upon the blood sugar and a greater amount is required to produce hypoglycemic convulsions if its administration has been preceded by an injection of pituitrin. Pituitrin also causes an increase in liver fat.

Geiling and DeLawder found that after the injection of pituitrin (or pitressin, p. 733) the muscles for a short time pass into a state suggesting that their activity was being carried on under anaerobic conditions. The blood issuing from the muscles was arterial in color, it had a low content of CO_2 and a high content of O_2 , glucose, lactic acid and inorganic phosphorus. The cardiac output and the total oxygen consumption fell. This phase was followed by one in which the conditions were reversed, the blood being more venous than usual. The cardiac output and the total oxygen consumption rose. The mechanism whereby these effects are produced, whether primarily metabolic or vascular in nature, is unknown.

(5) **MELANOPHORE-EXPANDING (-DISPERSING) PROPERTY.** In the skins of many cold-blooded animals are peculiar cells with branching processes and containing mobile pigment granules whose movement toward the periphery of the cell or toward the center is under hormonal influence. Such cells have been given the general name of *chromophores*. Those containing black pigment (melanin) are known as *melanophores* and those with red or yellow pigment are called *erythrophores* or *xanthophores*, respectively.

Hogben and Winton showed that pituitrin caused the pigment granules in the melanophores of the frog to become dispersed throughout the bodies and branching processes of these cells. This results in darkening of the skin. Thus, the injection of a drop or so of a solution of pituitrin into a frog causes its skin to become almost coal black as a result of the melanophore reaction. On the other hand, after hypophysectomy, owing to the disappearance of the pituitary hormone from the circulation, the pigment granules gather near the center of the cells and the skin becomes pale. Hypophysectomized tadpoles have, instead of the usual dark-brown or green color, a silvery appearance. The changes in color which certain amphibia, reptiles and fish undergo in

order to blend into the color of their surroundings is largely due to variations in the concentration of the pituitary hormone in the blood or to the balance between the concentrations of melanophore-expanding principle and adrenaline. Blinding frog deprives it of this adaptive power.⁵ Nerve impulses arising in the retina are believed, therefore, to govern the liberation of the melanophore-expanding principle. The production of melanin in the skin of the frog is said to be stimulated by this principle. It has also been found to accelerate *in vitro* oxidation of the tyrosine-tyrosinase system (p. 685).

In most animals, the melanophore-expanding principle is elaborated by the pars intermedia. Cultures of tissue from the pars intermedia also yield this principle, whereas, cultures of the neural part of the pituitary or of the anterior lobe do not. Nevertheless, the principle finds its way into the neural part of the pituitary and unpurified extracts of the latter always contain it as a contaminant. But it is possible to prepare it free from antidiuretic, pressor and oxytocic effects. Moreover, the melanophore dispersing action of extracts from different parts of the posterior lobe do not run parallel with the pressor, oxytocic and antidiuretic

⁵ The phenomenon of light influencing structure and function through the mediation of a retinohypophyseal mechanism is not peculiar to cold-blooded animals. The work of a number of experimenters indicates that the well known association of the seasonal periods with morphological changes (e.g., color and texture of hair or plumage) and with the sexual cycles of certain mammals and birds as well as with the migration of birds, is due, in part at least, to light acting upon the anterior pituitary through the medium of retinal impulses. Rowan, for example, was able to induce sexual activity in crows and canaries at any desired time of the year by varying the periods of their exposure to artificial light; it is also well known that the domestic fowl will lay regularly in winter if its period of exposure to light is lengthened by artificial means. Cognitive experiments have been carried out upon mammals: ferrets, hedgehogs and raccoons. The seasonal shedding of hair in the ferret has been shown to be conditioned by the length of the day; and optic nerve section or hypophysectomy abolishes the phenomenon. The sexual cycles are abolished, of course, by hypophysectomy (lack of gonadotropic hormone) but their periodicity in relation to the length of exposure to light is lost after optic nerve section alone. The extreme sensitivity to light of the pigeon in respect to the time of egg laying is extraordinary. The pigeon lays a pair of eggs in the morning, the second of the pair being laid with the regularity of clock-work half an hour after the first. Lengthening or shortening the period of exposure to light alters the duration of the interval between laying of the first and second eggs of the pair.

⁶ In those species such as the chicken, porpoise and whale which do not possess a pars intermedia, the melanophore-dispersing principle is found in extracts of the anterior lobe; none is present in the posterior lobe.

diuretic properties. These facts argue for the melanophore effect being due to a separate and distinct hormone. Zondek has given the name *intermedin* or the *chromatophorotropic hormone* to this principle. It has been suggested that the melanophore-expanding principle also causes the migration of the melanin granules in the pigment layer of the retina (p. 956) and is, therefore, a factor in dark adaption of the eyes of higher vertebrates, but the experimental evidence in respect to such a function is conflicting. Nor is there any definite evidence that any relationship exists between this hormone and the occurrence of retinitis pigmentosa (p. 742). It is natural that it should also be suspected of playing a rôle in cutaneous pigmentation in the human subject but again no reliable observation has been reported which might connect this principle with either normal or abnormal pigmentation in man.

Fractionation of the posterior lobe extract. Pitocin and pitressin

Considerable quantities of histamine may be present in commercial pituitary extracts which have not been carefully purified; indeed it was believed for a time by some (Abel and associates) that the plain muscle stimulating and depressor effects were due simply to histamine. Abel also maintained that the other effects (pressor and antidiuretic) were due to a single hormone. The work of Dudley, and especially of Kamm and his associates has shown that the specific effects are not due to histamine, and that there are at least two distinct active principles in a posterior lobe extract. From the crude extract Kamm and his associates have isolated two relatively pure fractions which are called, respectively, *pitocin* and *pitressin*. These are white amorphous powders freely soluble in water. Chemical analyses of highly purified preparations have revealed a high amino-acid content of both pitocin and pitressin; cystine, tyrosine and arginine are found in greatest amounts. Pitocin is the uterine-stimulating (oxytocic) principle and is 100 to 350 times more potent in this regard than the solution of Standard Pituitary Powder.⁷ It acts upon the

muscle of the uterine body but not upon that of the cervix. Pitressin is responsible for the vascular, intestinal-stimulating and antidiuretic effects. If a series of injections of pitressin be given at short intervals a certain degree of tolerance becomes established, the hypertensive effect being less with successive doses. Not uncommonly an initial fall in blood pressure preceding the pressor effect of a single injection occurs; this is attributed to a temporary sharp reduction in cardiac output due to coronary constriction. It is possible that the antidiuretic action of preparations of pitressin is due to a separate principle, for the pressor effect is more readily destroyed by heat than is the antidiuretic action. Preparations of pitressin with a pressor activity 300 times greater than that of a solution of Standard Pituitary Powder have been prepared.

Pitocin exerts its greatest effect upon the human uterus in the later months of pregnancy. In the first few months this principle exerts no oxytocic action, but a slight effect upon the uterus, probably of vascular origin follows the injection of pitressin at this time. In the fowl, pitocin causes a fall in blood pressure. From a practical point of view a great advantage has been gained by the separation of these two principles in relatively pure form, for the effect upon the uterus can now be secured without a rise in blood pressure which it is often advisable to avoid.

Either pitressin or pitocin causes hyperglycemia, but which one will have the greater effect depends largely on the species. In rabbits pitressin has the greater hyperglycemic action, whereas in dogs pitocin is more effective. The rise in blood sugar induced by these principles is due to the breakdown of glycogen (glycogenolysis) in the liver.

Functions of the posterior lobe

Though a posterior lobe extract when injected produces very definite effects, such might not represent the physiological actions of the gland within the body. In other words, the effects following injection might be due to substances which, though obtainable by extraction, were merely incidental and not principles of a true internal secretion. Proof that any given effect was hormonal would be the demonstration that removal of the gland produced a contrary effect which could be corrected in turn by injection of

⁷ A Standard Pituitary Powder with which the oxytocic and pressor activities of a given pituitary preparation can be compared is obtainable from the United States Bureau of Chemistry. The official solution of Pituitary (Posterior Pituitary Injection, U.S.P. XII) of the Pharmacopeia of the United States contains 5 mg. of the standard powder per cubic centimeter. An international unit of oxytocic activity or of pressor activity is defined as the amount of activity, oxytocic or pressor, respectively, obtained by the

extraction of 0.5 mg. of the standard powder. The official Solution of Pituitary therefore contains 10 international units per cubic centimeter. This is also the strength of commercial preparations.

the extract. There is little definite evidence, for example, that in mammals the posterior pituitary secretes a pressor substance which maintains the normal blood pressure; and little to suggest that it is concerned with capillary tone, as was suggested by Krogh from experiments upon the frog. It is true that in the latter species and in the toad the posterior lobe does appear to be essential for the maintenance of capillary tone. Dilatation of the cutaneous vessels occurs in these animals after total hypophysectomy but not after removal of the anterior lobe alone.

The isolation of an oxytocic principle from the posterior lobe led, as it was bound to do, to the theory that the elaboration and discharge of such a principle by the pituitary constituted an important factor in the birth mechanism, serving to stimulate the uterine contractions and expel the fetus at the end of the period of gestation. This conception of posterior lobe function, attractive and plausible though it was, appeared to be refuted by certain observations. Allan and Wiles, for example, reported that normal parturition occurs in hypophysectomized cats, and Selye, Collip and Thomson found that though the period of gestation in rats was prolonged after hypophysectomy, no abnormality in the birth mechanism was detectable. Bell and Robson demonstrated an oxytocic principle in the blood of pregnant cows, women in labor and in non-pregnant rabbits, but since there was no relation between the concentration of this substance and any period of gestation, concluded that it was not concerned in the initiation of labor.

Such negative findings aroused scepticism as to a physiological relationship between the pituitary and the parturient uterus. However, this uncertainty has been largely dispelled by recent work. Haterius and Ferguson, experimenting with rabbits from 2 to 80 hours *post partum*, observed increased frequency and amplitude of the uterine contractions upon electrical stimulation of the pituitary stalk. The response closely resembled that induced by pitocin and was obtained after spinal transection, vagotomy and severance of both splanchnic nerves. It was abolished by destructive lesions placed in the infundibulum. These results indicate that the oxytocic principle of the pituitary is a true hormone. The continuous activity of the uterus in the puerperal rabbit appears in the light of the results of later experiments of Ferguson to be due to pituitary secretion initiated reflexly from the pelvic viscera, for the contractions undergo progressive diminution in amplitude after inter-

ruption of the afferent pathways, by section of the pituitary stalk or of the spinal cord above the 12 lumbar segment. Fisher and his colleagues have also found previously that after section of the hypothalamohypophyseal tract in cats the expulsive movements of the uterus at term were extremely sluggish. We know that this operation reduces almost to the vanishing point the action of the principles of the posterior pituitary.

Other significant facts lending support to this conception of posterior pituitary function just outlined are, the insensitivity of the uterine cervix to pitocin, and the influence of the female sex hormones upon the action of the oxytocic principle, namely, the depression of uterine sensitivity by the latter induced by progesterin and the great sensitivity conferred by estrin (p. 748). Very suggestive in this connection, also, is the discovery of Cohen and Marrian (p. 749) that estrin is present in the blood and excreted in the urine as an inactive compound (glycuronide of estrin) in pregnancy until just before the onset of labor when it appears in the free (active) form.

Expansion of the melanophores in amphibia and of the erythrophores in the minnow is also undoubtedly a hormonal effect, as is also the *antidiuretic action*.

THE SOURCE OF THE POSTERIOR LOBE SUBSTANCE AND THE PATHWAY OF ITS SECRETION

This is a question which has not been finally settled. The earlier work of Herring, of Cushing and Goetsch and others suggested that the cells of the pars intermedia and pars tuberalis elaborate the hormone or hormones, and that the hyaline bodies (p. 722) seen in these regions represent ripened cells filled with secretion. Geiling and Oldham, on the contrary, are convinced that the pressor, oxytocic and antidiuretic hormones are formed, not in the pars intermedia, but in the posterior lobe itself. Since the discovery of neurohormones (e.g., acetylcholine and sympathin) the absence of tissue of a glandular nature from this part of the pituitary is no obstacle to the acceptance of such a view and, as Geiling points out, the adrenal medulla is of neural origin. Another reason for believing that the neurohormonal tissue, probably the pituicytes, elaborates the posterior pituitary principles is afforded by the experiments of Fisher and his colleagues already referred to. After section of the nerve fibers in the infundibular stalk degenerative changes confined to the posterior lobe appear, and the pressor, oxytocic and antidiuretic principles are greatly

minated, whereas the pars intermedia contains the normal amount of melanophore-expanding principle. Many believe that the hyaline bodies described by Herring are artifacts, but whatever their nature and function may be, an experiment performed by Maddock indicates that they traverse the posterior lobe and infundibular stalk to be discharged into the third ventricle. When a compressing clip was placed upon the infundibular stalk numbers of hyaline bodies gathered, although blocked, on the pituitary side of the clip. Injections of India ink particles have been seen to traverse the pars nervosa and stream up the stalk, which strongly suggests that this is the pathway taken by the posterior lobe hormones. Hyaline bodies in the act of discharging into the ventricle have also been described. Detection of the posterior pituitary principle in the cerebro-spinal fluid by means of the oxytocic and melanophore tests have been reported by some workers, others, however, have failed to confirm the observation. The recent experiments of Zondek indicate that oxytocin leaves the pituitary via the infundibular stalk. This principle was recovered from the walls of the third ventricle in the region of the autonomic centers but from nowhere else outside the pituitary.

Circumstantial evidence for the view that the posterior lobe hormone is discharged into the ventricular system has been furnished by Cushing. He found that the injection of commercial pituitrin into the lateral ventricle of man produced the most striking effects, which commenced within five minutes of the injection. These effects resemble in several respects those characteristic of parasympathetic stimulation, and are quite different from those resulting from the intramuscular injection of pituitrin. They include: (a) flushing of the skin and most profuse sweating, (b) fall in rectal temperature from about 99.0° to 94.0°, (c) nausea, vomiting and contractions of the small intestine, (d) rise in blood pressure after an initial fall and some increase in heart rate, (e) salivation and lacrymation, (f) fall in metabolic rate (from 3 to 31 per cent) within 1½ hours. These effects are not due to histamine. Comparable effects have been produced by Fulton in the monkey. The intraventricular injection of pilocarpine (a drug which stimulates structures innervated by parasympathetic nerves) causes comparable effects. Atropine, which abolishes parasympathetic effects, prevents the customary results following the intraventricular injection of either pituitrin or pilocarpine. Furthermore these agents have not their usual action in persons in whom the tissue

of the hypothalamic region has been destroyed by disease, or in persons under the influence of an anesthetic such as avertin, which is believed to act upon the hypothalamus. Penfield has reported manifestations similar to those described above in a patient with a lesion (tumor) in the region of the hypothalamic nuclei; he refers to the condition as *diencephalic autonomic epilepsy*. On the basis of his results Cushing conceives that the secretion of the posterior lobe passes into the cerebro-spinal fluid of the ventricle and diffuses through the nervous tissue to act upon the parasympathetic center in the hypothalamus (tuber cinereum). On the other hand, the secretion of the posterior lobe is controlled by impulses arising in higher nervous centers and relayed to the gland through the hypothalamic nuclei (see p. 882). This conception of a nervous-hormonal synergism finds its analogy in the sympatho-adrenal system in which impulses flowing along sympathetic pathways cause the liberation of adrenal secretion, which in turn reinforces the action of the sympathetic.

DISORDERS OF THE PITUITARY IN MAN

Derangements of pituitary function may take the form of overactivity or of deficiency. In the former case tumors composed of functioning endocrine tissue are frequently the cause of the disorder; in the latter, atrophy or degeneration of the specific secreting cells, either primarily or as the result of mechanical pressure by tumors, may be responsible. A pituitary tumor of the anterior lobe may be composed of any of the cellular elements of the gland—*chromophobe*, *acidophil* or *basophil* adenomas. Squamous-celled growths (craniopharyngeomas) may also arise from epithelial rests—remnants of Rathke's pouch—near the root of the infundibular stalk. As a result of the confined position of the pituitary within the sella turcica the entire gland is likely to suffer from pressure effects when one of its parts becomes enlarged. For this reason and on account of the proximity of other important structures, e.g., hypothalamus and optic chiasma, and the proclivity of tumors to invade or press upon neighboring structures, the manifestations of a pituitary tumor are not always referable simply to the part of the pituitary originally involved. Any function—growth, sex, water elimination, or the metabolism of carbohydrate or fat, presided over by the pituitary-hypothalamic mechanism may therefore be disturbed by a lesion in this region. Nevertheless, the site wherein the tumor arises

The following is a short classification of pituitary disorders—

Anterior lobe	{	overactivity	{ Acromegaly Giantism Pituitary basophilism— Cushing's disease
		deficiency	{ Dwarfism Pituitary cachexia— Simmond's disease Acromicria
Posterior lobe deficiency or hypothalamic lesion			Diabetes insipidus
Anterior lobe deficiency together with posterior lobe deficiency or hypothalamic lesion			Dystrophia - adiposo-genitalis (Fröhlich) (a) Infantile or juvenile type (b) Adolescent or adult type

ACROMEGALY

This condition was first described by Pierre Marie in 1885. It is due to the excessive elaboration of the growth hormone (p. 724) during adult life, i.e., after the usual age of full skeletal growth (fig. 290). An adenomatous tumor of the anterior lobe composed of acidophil cells is responsible for the hypersecretion. The characteristic features of the condition are: (a) overgrowth of the bone

FIG. 290. Acromegaly, together with enlarged stature—acromegalic giantism. (After Cushing and Davidoff.)

FIG. 291. Skulls of a normal person (left) and of an acromegalic (right). (After Cushing and Davidoff.)

and the nature of the cells of which it is composed do very often determine the predominant features of the condition, and certain fairly well defined groups of symptoms (syndromes) are recognized. To these may or may not be added symptoms referable to pressure upon, or to irritation or destruction of, near-by nervous structures.

of the hands, feet and face. Of the latter, the mandible, nasal bones and supraorbital ridges are especially involved (fig. 291). The feet and hands are greatly increased in size, the latter being usually broadened and the fingers thickened. Under the X-rays, the terminal phalanges appear tufted, thus resembling a wheat-sheaf in shape.

bowing of the spine (kyphosis) is common. The soft tissues of the nose, lips, forehead and scalp are thickened, the latter being thrown into folds or wrinkles (bulldog scalp). There is a general overgrowth of body hair. (b) Atrophy of the gonads and suppression of the sexual function (amenorrhea in women, impotence in men). In the earlier stages there may be evidence of increased sexual function. (c) Enlargement of the viscera (splanchnomegaly). The tongue, lungs, thymus, heart, liver and spleen are greatly enlarged. The thyroid, parathyroids and adrenals may show hypertrophy or adenomatous growths. Hyperthyroidism may be present in the early stages. (d) Glycosuria and hyperglycemia are common, and a condition indistinguishable from diabetes of pancreatic origin may be present. The metabolic rate may be raised by from 10 to 70 per cent; the specific dynamic action of protein is not altered (p. 554).

GIANTISM

Giantism is due to a pituitary lesion of a similar nature to that responsible for acromegaly, but the condition arises in pre-adult life, i.e., before ossification is complete (fig. 292). A general overgrowth of the skeleton results and the production of persons of enormous stature—7 or 8 feet or more in height. The limbs are usually disproportionately long. The viscera are not enlarged out of proportion to the frame unless, as is sometimes the case, the giantism is accompanied by the characteristic features of acromegaly, as may occur after adolescence.

PITUITARY BASOPHILISM (CUSHING'S DISEASE)

This very rare condition is generally attributed to an anterior lobe adenoma composed of basophil cells⁸ (fig. 293). Its main characters are: (a) Obesity of the trunk (especially of the abdomen), face and buttocks, but not of the limbs. The fatty deposits are frequently tense, tender and painful. Purplish striae, due to distention, are present over the lower abdomen. (b) Cyanosis of the face, hands and feet, pigmentation of the skin and excessive growth of hair. Women may grow a mustache or a beard. (c) Loss of mineral from

⁸ Susman found, however, that in the postmortem examination of a large number of pituitaries, small basophil adenomas were present in 3.1 per cent, though no signs of basophilism was observed during life. Crook also states that a basophil adenoma or a general increase in basophil cells is an inconstant finding in Cushing's syndrome, but that hyaline degeneration of these cells (with or without adenoma) is invariable.

the bones, with softening or brittleness. The softening often involves the dorsal vertebrae and leads to kyphosis. (d) Vascular hypertension. (e) Suppression of sexual functions. (f) Hyperglycemia and glycosuria and in some cases increased urinary excretion of nitrogen. (g) Atrophy of testes or ovaries and sometimes hypertrophy of the adrenals (cortex or medulla or both). In view of the commanding position which the pituitary occupies in the endocrine system it is highly probable that some of the features of the condition are due to the secondary disturbances in the functions of other endocrines. The skeletal

FIG. 292. Giantism. (After Best and Taylor, *The Human Body and its Functions*.)

decalcification, for example, suggests parathyroid overactivity, nevertheless such a relationship is not indicated by histological examination of the parathyroids in subjects of basophilism, degenerative rather than hyperplastic changes in these glands having been observed. The depression of the sexual functions and genital atrophy are difficult to explain, since they are the reverse of what might be expected from the supposed functions of the basophil cells (p. 756). It is possible, however, that the changes seen in the parathyroids and gonads represent an exhaustion atrophy resulting from overstimulation. The vascular hypertension and the adrenal hypertrophy already

mentioned strongly suggest that the adrenals are overstimulated by the pituitary excess. Moreover, primary disease of the adrenal cortex (e.g., tumor) may produce a clinical picture almost indistinguishable from that of pituitary basophilism (fig. 274, p. 698). In other words, some of the outstanding clinical features of the condition termed pituitary basophilism are due directly, apparently, to adrenal activity and may therefore arise either from primary adrenal disease, or secondarily as a result of a basophil tumor of the pituitary.

FIG. 293. Pituitary basophilism. On left, at 20 years of age; right, 5 years later at height of the disease. (From Cushing, after Turney.)

DWARFING

The arrested skeletal development which results from deficiency of the growth hormone of the anterior pituitary is spoken of as the *Lorain* type of infantilism (fig. 294). These dwarfs are usually, though not invariably, undeveloped sexually. They do not show deformity or as a rule mental inferiority, and are generally not unattractive in appearance. Sometimes, however, they are wizened and except for their miniature stature appear older than their years (*progeria*). The anterior lobe dwarf at adult age may be no more than 3 or 4 feet in height. During infancy and childhood, the ossification centers as observed by radioscopy appear normal and dentition is not delayed. The relative proportions of the different parts of the skeleton are not far from normal though they tend toward those characteristic of childhood, the head being large relatively to the

body. Some encouraging results have been reported from the treatment of this type dwarfism during early childhood with anterior pituitary preparations.

According to Evans the dwarfing seen in cretinism is also due essentially to pituitary deficiency—a result of the absence of the normal stimulative effect of the thyroid hormone upon hypophyseal function. (See footnote, p. 725.)

FIG. 294. Infantilism due to anterior lobe deficiency. Age 21 years. Man on right, 5 feet 7 inches. (After Lisser.)

PITUITARY CACHEXIA (SIMMONDS' DISEASE)

This rare disease was first described by Sir Simonds of Hamburg. It is due to atrophy and degeneration of the anterior lobe. The main features of this disease form a picture which may be best described as that of a premature and rapidly developing senile decay (fig. 295). This may be briefly summarized as follows:—
General appearance—loss of axillary and pubic hair; hair of the head prematurely gray and sparse; loss of teeth; skin of face wrinkled and dry; of great emaciation; smallness of hands and feet and shrunken appearance of the facial features. (a) *Anemia*. (c) *Low metabolic rate and hypoglycemia*.

Amenorrhea or impotence. (e) *Mental deterioration, muscular weakness, death in coma.* (f) *Atrophy of the gonads and a general smallness of the internal organs (splachnomicria).*

Acromicria. This is the antithesis of acromegaly. The bones of the face and extremities are small, delicate and fragile. Other features are, loss of hair, depression of sexual functions and cyanosis of the extremities. It is due probably to disease of the acidophilous elements of the anterior lobe with consequent deficiency of the growth hormone. It occurs in adults, and is, after the period of skeletal growth, and thus bears the same relationship to dwarfism as acromegaly bears to giantism.

FIG. 295. Pituitary cachexia. Photograph on left, patient aged 42 years; photograph on right, the same man at the age of 34 years. (From Zondek. *Disorders of the Endocrine Glands*, Arnold, London.)

DIABETES INSIPIDUS

Diabetes insipidus is a condition in which large quantities of urine of very low specific gravity, 1.002 to 1.006, and low chloride content, are excreted. In an ordinary case the daily output of urine is 4 or 5 liters, but daily amounts several times these figures have been reported. A corresponding increase in the fluid intake occurs and thirst is often intense. The condition frequently accompanies tumors of the pituitary or hypothalamic region. It has been ascribed to posterior lobe deficiency, since it is relieved by injections of pituitrin and in earlier experiments upon animals was a common result of hypophysectomy. It has been shown, however, by Bailey and Bremer, and later by others, that in animals puncture of the hypothalamus in the region of the tuber cinereum without any apparent injury to the pituitary causes polyuria. Diabetes insipidus also ensues in conditions (epidemic encephalitis) involving the hypothalamic region. On the other hand, the

aforementioned antidiuretic effect of pituitrin and the experiments of Maddock, in which the condition was induced in animals by the application of a clip to the pituitary stalk, point to deficiency of the posterior lobe of the pituitary as a factor. It is more correct, however, to look upon diabetes insipidus as the result of a disorder affecting the integrity of the hypophyseal-hypothalamic mechanism rather than as being dependent specifically upon either the pituitary or the hypothalamus. Involvement of one or other element, or of the nervous connections between the two would therefore cause the disease. Fisher, Ingram and Ranson found, for example, that a lesion interrupting the supra-optico-hypophyseal tract of nerve fibers resulted in diabetes insipidus together with atrophy of the cells of the supra-optic nucleus and of the posterior lobe of the pituitary. The atrophic posterior lobe was found to be almost devoid of antidiuretic, oxytocic and pressor principles.

The failure of total hypophysectomy to produce diabetes insipidus is due, according to the widely accepted theory of von Hann, to the secretion by the anterior lobe of a hormone which antagonizes the post-pituitary antidiuretic factor, i.e., to the production of a *diuretic* principle. Von Hann based his view on the postmortem records of twenty subjects with lesions involving the posterior lobe. In nine, no functioning anterior lobe tissue remained and these had not suffered from diabetes insipidus. The experimental results of Richter accord with these findings. Total hypophysectomy in rats was in no instance followed by permanent diabetes insipidus, whereas this condition was invariably produced by removal of the posterior lobe alone. This theory implies that the excretion of water by the kidney is normally governed through a nice balance established between the activities of the anterior and posterior lobes—a balance which is upset by (a) removal of the latter, (b) by interruption of its nerve connections with the hypothalamus, or (c) by the injection of an anterior lobe extract after total hypophysectomy. It has been found that an intact thyroid gland is necessary for the experimental production of diabetes insipidus; the condition once established is abolished by thyroidectomy, but can be induced again by thyroid administration. An experiment performed by Keller suggests that the diuretic action of the anterior lobe is brought about through its thyrotropic hormone. When anterior lobe extract was administered daily to a hypophysectomized animal the water intake did not show

the anterior lobe of the pituitary, which accounts for the sexual immaturity and dwarfing, and of the hypothalamus (or posterior pituitary). The experiments of Smith with hypophysectomized rats and of other investigators point to injury of the hypothalamus rather than of the posterior lobe being chiefly responsible for the obesity. Marked obesity is also a feature of certain hypothalamic disorders in man unassociated apparently with any disease of the pituitary itself. *Dysphagia adiposo-genitalis* appears in two forms according to the age at which it develops—the *infantile* or *prepuberal* and the *adolescent* or *adult*.

FIG. 297. Male aged 8. Hypopituitarism following whooping cough, with characteristic growth and sex defects and obesity; Fröhlich's syndrome. (After Gardiner-Hill.)

THE INFANTILE OR PREPUBERAL TYPE (fig. 297). This type may occur in children of any age before puberty. It may be the result of an inherent defect of the pituitary, of atrophy of the secretory cells by pressure (e.g., by tumors), injury (e.g., a penetrating wound) or of some infectious disease. Polyuria and a high sugar tolerance are frequent accompaniments of the disease. The subjects are lethargic or somnolent and often of subnormal intelligence. They usually have voracious appetites and especially a craving for sweets. The "fat boy" of *Pickwick Papers* was undoubtedly an example of this condition. The younger the age of the child at which the disease commences the greater, obviously, will be the degree of stunting. When the dwarfing is of high grade this

combined with the obesity makes a very striking picture. These subjects are human counterparts of Smith's rats in which the pituitary was destroyed (and the hypothalamus presumably injured) by chromic acid injections.

FIG. 298. Extreme case of obesity, due to pituitary or hypothalamic disease. (After Timme.)

FIG. 299. Laurence-Biedl-Moon syndrome. Note the presence of six toes. (After Weiss.)

The name of Brissaud is sometimes associated with the disease as seen in children around the age of puberty.

THE ADOLESCENT OR ADULT TYPE. Male subjects of this condition are often effeminate in disposition and appearance. The excess fat has a feminine distribution, the adiposity being notice-

able chiefly in the mammary region, buttocks, thighs and over the mons veneris. The hair over the pubis and in the axillae is sparse or absent; the skin of the face and the body is smooth, soft and hairless; the hips are broad. In female subjects the obesity is often extreme, a weight of 300 pounds being not very unusual (fig. 298). In both sexes the feet and hands are small and "pretty," the finger tips being slender and tapering with narrow pointed terminal phalanges. The extremities thus give a picture the reverse of that seen in acromegaly. The basal metabolic rate is often subnormal and sugar tolerance increased.

Diabetes insipidus is a common, and narcolepsy (p. 884) an occasional, accompaniment.

LAURENCE-BIEDLE-MOON SYNDROME

This condition, hitherto attributed to pituitary deficiency, is now believed to be due to involvement of the hypothalamus. Since it bears resemblance to the condition described in the last paragraph it is convenient to consider it here. The chief features of the disease are: obesity, sexual infantilism, retinitis pigmentosa, polydactylism, mental deficiency and a family tendency (fig. 299).

CHAPTER LXII

THE ENDOCRINE ORGANS OF SEX. THE THYMUS AND PINEAL GLANDS

THE CHARACTERS OF SEX

The sex glands—testes or ovaries—are known as the *gonads*. They are the *primary organs of*

They furnish the male or female sex cells (spermatozoa or ova) upon which the *ultimate* maleness or femaleness of the animal depends.

The sex, and so the type of sex gland, which is developed is ordained, however, at the earliest possible time in the history of the individual, namely, when the parental ovum and spermatozoon conjugate. The determining factor is the type of chromosome (X or Y) in the sperm cell. The cells of the human body possess 48 chromosomes—24 pairs. In the case of the male one of these pairs contains a small chromosome, designated Y. The other chromosome of this pair is large like those in the other pairs and is referred to as X. In the female, the chromosomes in all pairs are the same, that is, X chromosomes. When the male and female germ cells mature each receives only half the number of chromosomes. Some sperm cells will therefore contain a Y, others an X chromosome. An ovum, of course, can contain only an X chromosome. Fertilization of an ovum by a sperm cell possessing a Y chromosome, results in a zygote containing a chromosome of each type. The body cells of the individual to which this cell ultimately gives rise will therefore contain each a pair of XY chromosomes; the offspring will be male. If the ovum is fertilized by a sperm cell containing an X chromosome the offspring will be female (XX). Certain diseases and defects are linked with the X chromosome of the male. Among such sex-linked diseases are hemophilia and color blindness. They appear in the male but are transmitted by the female who does not herself show the disease. For example, a man afflicted with hemophilia if he marries a normal woman does not transmit the disease to his sons (XY), for the X chromosome received from the mother does not carry the defect, nor does the Y chromosome derived from the father. The daughters, however, have received an abnormal character in the X chromosome derived from the father as well as a normal one from the mother. But, since the abnormal character is recessive, it is "suppressed" by the dominant normal character,

and the daughters are free from the disease, though their cells must contain the chromosome carrying the defect. When therefore the daughters marry and an ovum is fertilized by a sperm cell containing an X chromosome the daughters of the next generation again show no abnormality; but should a Y sperm fertilize the ovum and an XY (male) zygote result, the child will show the disease if one of the abnormal X chromosomes of the mother has paired with the Y from the father. The Y chromosome does not offset the effect of the abnormal X chromosome. It should be remembered that since the mother possesses two X chromosomes, a normal and an abnormal one, it is an even chance which one the child will receive.

Those organs, other than the sex glands, which are essential for procreation, such as the external genitalia, as well as the uterus, Fallopian tubes and vagina of the female and the seminal vesicles and prostate of the male, are spoken of as the *accessory organs of sex*. Other characters of sex only make their appearance at the time of sexual maturity (puberty), e.g., the growth of hair upon the pubis of the human male or female, the development of the mammary glands in women, the development of the antlers of stags, the distinctive plumage of birds and the psychic manifestations of sex in man and in animals. These are spoken of as the *secondary sex characters*.

EFFECTS OF EXCISION OF THE SEX GLANDS OR GONADS—CASTRATION—SPAYING

Removal of the gonads (castration) from a young animal prevents the mature development of the accessory sex organs and the secondary sex characters fail to make their appearance. The effects of castration upon the secondary characters are evident even in such simple animal forms as the earthworm and the hermit crab. Castration of male frogs prevents the appearance of the sexual changes which normally occur during the mating season. The thumb-pad and the fore-limb muscles do not hypertrophy, the clasping reflex cannot be elicited and the animal does not emit its characteristic croaking sound. Transplantation of the excised testicular tissue into another part of the animal's body prevents the occurrence of these

castration effects. The sexual development of birds and mammals is profoundly affected by castration. The castrated Leghorn cockerel (capon), for example, has a greater proportion of body fat than the normal bird, while the comb, wattles and barbles, and the sex instincts do not develop. Development of the spurs and plumage, however, is not prevented. Corresponding effects of gonadectomy are seen in the young turkey-cock and in the young of other avian species. Removal of the ovaries from the young hen (spaying)¹ causes the development of spurs, a comb resembling that of the cock, and male plumage. The spayed duck assumes the plumage of the drake.²

The effects of castration upon young cattle, horses and stags are well known. Castration of young bulls causes an increase in size of the skeleton and a greater deposition of fat. The mature development of the accessory organs is prevented. The antlers of young stags do not develop after castration and female deer after atrophy or disease of the ovaries may develop horns. Castration of boys before puberty retards ossification of the epiphyses of the long bones with consequent enlargement of the stature. The lower limbs become disproportionately long. There is also adiposity, the fat tending to become feminine in distribution. The larynx is not prominent as in the mature male and the voice remains high-pitched. The hair fails to grow upon the face and body, but is unusually plentiful on the head. The penis remains infantile and sexual feeling is suppressed. Ovariectomy is followed by corresponding effects; if performed before puberty the characteristic feminine attributes do not appear, the girl tends to become mannish in type, the accessory organs fail to develop fully and menstruation does not occur. In animals subjected to this operation before puberty the estrous cycles do not ensue. If the operation is performed after puberty the estrous cycles are suppressed and the accessory organs atrophy. In women after the age of puberty ovariectomy is followed by changes characteristic of the menopause (p. 762), namely, amenorrhea, atrophy of the sex organs and obesity.

Sex desire in higher animals and in the human subject is not, apparently, dependent entirely

upon the gonads, for it is sometimes retained in eunuchs and in women who have been ovariectomized after marriage though removal of the ovaries before puberty, i.e., before the accessory organs of sex have reached maturity, or in virgin women after puberty, suppresses the libido. Stone found that a certain proportion of a series of male rats castrated after sexual maturity had been attained, pursued the female and were capable of copulating during a subsequent period of eight months. Rowe also cites the instance of a man in whom the sex libido was not abolished twenty-five years after the testes had been excised. Prepuberal removal of the testes prevents the development of sexual desire.

The freemartin

The effect of the secretion of the gonads upon the sexual development of the embryo is shown in the case of twin calves when these are of opposite sexes. In such cases the male twin is always normal but the female, in the majority of cases, shows abnormalities of the accessory organs. The uterus is small and underdeveloped, the clitoris is enlarged and penis-like; the gonads are rudimentary and may resemble testicles and in some instances structures resembling vasa deferentia and seminal vesicles are present. The abnormal female showing such intersexual characters is called a *freemartin*. Keller and Tandler in Austria and Lillie in America have made a study of a number of such cases. They found that as a result of the fusion of the chorions, a direct communication between the circulations of the male and female embryos exists. According to Lillie, the fusion of the chorions is seen at an early stage of development, when the embryo is no more than 10 or 20 mm. long. In the rare case in which the female twin was normal a communication between the two circulations did not exist and no masculinization of the female twin is therefore attributed to the action of the internal secretion liberated by the gonads of the male. In order to explain the fact that masculinization of the female occurs but never feminization of the male, it is supposed that the hormone of the testis is elaborated at an earlier stage of development than is that of the ovary. Masculinization of guinea-pigs has been induced by the injection of testicular hormone into the fetuses *in utero* (Dantchakoff). Ivy and his colleagues produced corresponding effects in rat fetuses by means of male hormone treatment of the mother during gestation; feminization of male fetuses was also effected by antenatal treatment with female hormone (oestradiol-dipropionate, p. 749).

Transplantation or grafting experiments

If the excised sex gland (testis or ovary) is transplanted to another situation in the body and the otherwise inevitable effects of castration are prevented. This fact, first demonstrated by Lillie

¹ The terms ovariectomy and castration are also applied to this operation.

² Male plumage is considered to be the basic or neutral type. Its development is suppressed by the female sex hormone, the female type of plumage then appearing. Hence it is that male plumage appears after ovariectomy and persists after removal of the testes.

449, proves conclusively that the sex gland (male or female) furnishes an internal secretion. Transplantation of the gland from its normal position into a new situation in the same animal is called *autotransplantation*. The grafted tissue usually lives. This operation has been performed in the human female after the apparent complete excision of the ovaries. Fertility resulted. The grafting of the gonad into a new animal of the same species is called *homotransplantation*. This operation is not so successful, though a certain proportion of homotransplants survive and perform their functions, for a time at any rate. This way feminization of the capon or masculinization of the bilaterally ovariectomized hen can be effected by the transplantation of the gonad of the opposite sex. Transplantation of the gonad into the body of a member of another species is known as *heterotransplantation*. It is the least successful type of transplantation. In some cases, however, histological evidence of the survival of the transplant for some months has been obtained, but atrophy occurs eventually.

Development of the gonads

The ovaries and testes arise from the celomic epithelium covering the inner aspect of the Wolffian duct. The epithelial cells of this region assume a columnar form; they proliferate to form several layers which constitute the *germinal epithelium*. The mesoderm underlying the germinal epithelium becomes thickened to form the *genital ridge*. Fingers of mesoderm grow upwards into the overlying germinal epithelium while columns of the latter cells grow into the mesoblastic tissue. There is thus an interlocking of epithelium and mesoblastic cell masses. The epithelial columns, or *genital cords*, as they are called, later become broken up into *cell nests*. From these, the *Graafian follicles* of the ovary or the *seminiferous tubules* of the testes are developed. A layer of the germinal epithelium also comes to cover the surface of the ovary. The mesoblastic tissue surrounding the islands of the primitive gonad gives rise to the stroma and vascular tissue of the ovary or testis.

Structure of the ovary. The adult ovary is about the size and shape of a shelled almond and consists of a stroma of connective tissue which carries the blood vessels and in which are embedded a number of follicles called the *Graafian follicles*—in different stages of development. The stroma also contains a few smooth muscle fibers. The surface of the ovary is covered with a layer of epithelial cells—the *germinal epithelium*—continuous with the epithelium of the general peritoneum. Irregular groups of epithelial-like cells are also scattered throughout the ovarian stroma of many animals. Groups of these so-called *interstitial cells*, absent from the human ovary, though scattered throughout, are similar in appearance, and probably also in function, are present.

The Graafian follicles. Just as in the embryo, the germinal epithelium sends columns of cells into the underlying mesoderm, so in later life the germinal

epithelium covering the ovary sends small groups of its cells into the ovarian stroma. One cell of the group develops into a primitive ovum around which the remainder become arranged in a circular row. This body—the *primordial follicle*—which so far has no cavity and is about 0.5 mm. in diameter, migrates deeper into the stroma. Two more layers of cells derived from the surrounding stroma are now formed which encircle the ovum and the layer of cells immediately in contact with it. The outer of these layers—the *theca externa*—is fibrous; the inner—the *theca interna*—is vascular and more cellular. The original layer of cells in immediate contact with the ovum at the same time multiply to form a mass of cells several layers deep in which two concentric zones can soon be

FIG. 300. Section of ovary of rabbit. A, germinal epithelium; a, young primordial Graafian follicle; b, ovum in mitosis; d, another primordial follicle but more advanced; c, ovum with membrana granulosa; m, ovum almost mature with discus proligerus (i) and membrana granulosa (b). (After Cajal, Textbook of Histology.)

distinguished. Later, these become partly separated from one another by the collection of fluid (liquor folliculi) between them to form an inner and an outer zone. The inner-zone in immediate contact with the ovum is called the *discus proligerus* (fig. 300). The outer zone forms a lining for the maturing follicle and is known as the *membrana granulosa*. As it becomes larger and the changes just described, which are spoken of as *follicular maturation* or *ripening*, progress, the follicle migrates again outwards, and when quite matured projects from the surface of the ovary. Rupture of the follicular wall follows and the ovum, which in the meantime has undergone partial maturation (extrusion of first polar body) is discharged and conveyed along the Fallopian tube to the uterus. The subsequent history of the Graafian follicle is given on page 750. Large numbers of small follicles containing immature ova are present in the ovary from birth. Ripening of the follicle and discharge of the ova do not occur, however, until puberty. In the mature ovary there appear at regularly recurring periods crops of

premordial follicles. But only a small proportion of these advance to complete maturation and discharge their ova. In the human species, no more than one or two ova are as a rule discharged each month. The remaining follicles reach various stages in the ripening process and then undergo degenerative changes (*atretic follicles*). Each of the latter is finally replaced by fibrous tissue derived from the theca interna, a small scar (*corpus fibrosum*) alone remaining. The factors which determine the rupture of the ripe follicle are not definitely known. The accumulation of fluid and the consequent increase in intra-follicular pressure is probably a factor in some animals, or the contraction of the smooth muscle fibers of the stroma may play a part. In most species, including man, the follicle ruptures spontaneously, but in the rabbit, cat and ferret ovulation occurs only after copulation.

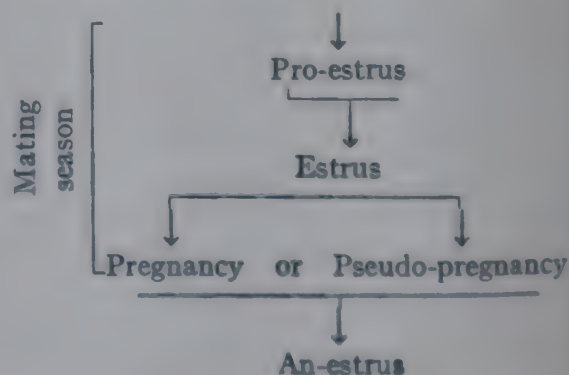

THE SEXUAL LIFE OF FEMALES

Three sexual periods of different lengths occur in the female mammal: (1) A single long period occupying the greater part of the animal's life. It commences at *puberty*, at which time the first ovulation occurs, the accessory organs of reproduction mature, sex desire is aroused and the secondary sex characters appear. It ends with atrophic changes in the ovary and accessory organs. In women the termination of this period is called the *menopause* (p. 762).

(2) A period which recurs once or oftener each year, known as the *mating* or *breeding season*. In most species it is only during this time, or during a part of it, that the female will receive the male. The duration of the mating season and the number of times it occurs annually vary in different species. In the dog, for instance, two such periods of about six weeks' duration occur each year (spring and autumn), while in certain other species they occur more frequently, and in others again only once, and may be of long or of short duration. In the human, reproduction is not confined to any one part of the year, though a study of birth statistics shows that fertility is greatest at certain periods (April to June). It has been suggested that in primitive man a mating season corresponding to this time of year did exist.

(3) *The estrous cycles*. These are periods of sexual activity which in animals occur once or oftener in each breeding season. The first cycle commences at puberty. In women, higher monkeys and anthropoid apes they are represented by the menstrual periods. Animals such as the bitch, in which a single estrous cycle extends throughout the breeding season, are called *monestrous*. *Poly-estrous* animals, on the other hand, are those such

as the domestic cat, the mare, cow, sow, rat and mouse, in which two or more cycles, separated by short periods of sexual quiescence, occur in succession during the breeding season. In a monestrous animal the following phases of the estrous cycle are distinguished. (a) *Pro-estrus*, or period of "coming on heat." There are usually swelling and congestion of the external genitalia together with growth and increased vascularity of the uterus. There is, as a rule, some enlargement of the mammary glands and, in the dog and cow, bleeding from the vagina. During this stage of the cycle the Graafian follicles are undergoing maturation preparatory to rupture. (b) *Estrus*,³ or "period of desire." The female receives the male and ovulation occurs. The term "heat" is commonly applied to the combined periods, pro-estrus and estrus. (c) *Pseudo-pregnancy* or *pregnancy*. The changes in the uterus initiated during the previous periods progress and in some animals, e.g., the bitch, rabbit and ferret, there occur pronounced proliferation and secretory activity of the uterine glands, hypertrophy of the mucosa and a great increase of the uterine blood supply. The growth of the mammary glands is stimulated. This phase of the sexual cycle is known as pseudo-pregnancy. The uterine changes, which are similar to those occurring in the premenstrual period of the human subject are looked upon as anticipating the arrival of a fertilized ovum. If this fails to ensue the newly-formed uterine fabric breaks down, the debris is discharged and the uterus returns to its resting state. If impregnation of the ovum occurs the uterine changes persist and merge into those characteristic of the pregnant state. (d) *Anestrus* is the period of sexual quiescence. It follows pregnancy or pseudo-pregnancy and coincides with the period elapsing between either of these periods and the next mating season. The monestrous cycle may be illustrated as follows.

³ *Estrus*, L = *gad-fly*, with figurative meaning of frenzy or intense desire.

polyestrous animals the short intervals of quiescence separating the estrus cycles are called *anestrous periods*. The term *anestrus*, as in the case of monestrous species, refers to the longer periods of rest between the mating seasons. Copulation and pseudo-pregnancy do not occur spontaneously in certain animals, e.g., cat, rabbit and ferret, but only after copulation. Though the onset of estrus in some species is quite obvious, in rodents it is difficult to detect by the ordinary means. Stockard and Papanicolaou, however, discovered that the vaginal mucosa of the guinea pig underwent certain changes (cornification of epithelium and disappearance of leucocytes) coinciding with the onset of estrus. Similar changes occur in the vagina of the rat and mouse. By the examination of a smear of the vaginal secretions the stages of the estrous cycle can be readily followed in these animals. Leucocytes which are present in smears taken during the anestrous or anestrus period are absent from the vaginal secretions during pro-estrus and estrus, but large squamous (cornified) cells appear.

OVARIAN HORMONES

These are: (1) *estrin*, also known as the *follicular hormone* or *female sex hormone*, and (2) the *corpus luteum hormone* or *progestin*. The follicular hormone is concerned particularly with the first part of the estrous cycle, the corpus luteum hormone with the latter part (pseudo-pregnancy), and with the pregnant state.

ESTRIN—THE FOLLICULAR HORMONE

The evidence derived from ovariectomy and transplantation experiments had made it clear that the ovary furnished an internal secretion which was responsible for the sexual development of the female, yet the results of experiments with ovarian extracts had been inconclusive until the work of Allen and Doisy in 1923. They obtained a potent ether extract from the liquor folliculi aspirated from hog's ovaries which was capable of inducing estrus in immature animals. The success of these workers was to a large extent due to the employment of a precise method for the demonstration of estrus, namely, the vaginal smear technique described above. Other investigators, for the most part, had relied upon uterine effects as a means of testing the activity of their extracts. The name *oestrin* was suggested by Parkes and Bellerby for this ovarian hormone. It is usually called estrin on this side of the Atlantic.

The physiological action of the follicular hormone may be listed as follows: (1) It induces estrus in immature animals and in ovariectomized adult animals, or in normal adult animals during anestrus; there result in consequence, hypertrophy of the uterus and proliferation of its glands (fig. 301), vaginal changes, growth of the mammary glands (p. 765), rhythmical contraction of the muscle of the uterus and Fallopian tubes, psychic and other phenomena associated with the estrous period; it sensitizes the uterine muscle to the action of pitocin. (2) It prevents the otherwise inevitable atrophy of the accessory reproductive

FIG. 301. Effect of injection of follicular extract into eight-week-old rabbits. Animals were litter sisters. No. 807 received 2 mg. of extract No. 805 not injected and killed at the same time as No. 807 for control. No. 806 received 1 mg. of extract daily for four days and No. 809 1 mg. daily for eight days. No. 808, uninjected control, killed on same day as No. 809. (After Doisy, Ralls, Allen and Johnston.)

organs in ovariectomized animals. (3) It is believed to be responsible for the development of the secondary sex characters which in some species are such prominent features of the mature female. (4) Its injection into the adult *male* rat induces retrogressive and degenerative changes in the genitalia, and retards the development of sexual maturity in immature male rats; it causes atrophy of the cock's comb. These "antimasculine" effects are probably exerted through the inhibition of the gonadotropic activity of the anterior lobe of the pituitary (p. 753). The growth effect of the pituitary is also abolished, but thyrotropic activity is unaffected. Zondek found that prolonged treatment with estrin causes great enlargement of the

pituitary which contains large amounts of gonadotropic and growth principles; estrin, therefore, apparently effects the utilization or liberation, rather than the production of these factors. (5) Estrin is believed to be largely responsible for the enormous growth of the uterus during pregnancy. When pregnancy is confined to one horn of the rabbit's uterus, that horn alone increases in size. It is thought therefore that estrin, which is in high concentration in the placenta, may act locally upon the uterine tissue rather than through the general circulation. On the other hand, it may well be that the mechanical effect of distension is necessary for sensitization of the uterus to the action of the hormone, for the introduction of paraffin pellets of a certain size into the uterine cavity induces a localized hypertrophy. Estrin does not stimulate the ovaries; continued injections actually reduce the size of the latter and of the testes, an effect attributed to suppression of the gonadotropic principle of the pituitary. (6) Estrin exerts no notable effects upon the circulation, respiration, body growth or basal metabolic rate. (7) If, after menstruation has been abolished in monkeys by ovariectomy, a series of injections of estrin is given and then stopped abruptly, menstruation occurs a few days later. During the estrin treatment of these ovariectomized animals, phenomena appear, analogous to those appearing during the estrous period of lower animals, e.g., endometrial changes, redening and swelling of the external genitalia, and the vaginal smear shows cornified cells and the absence of leucocytes. (8) A synergic action between estrin and the oxytocic principle of the posterior pituitary has been demonstrated; after the administration of estrin to a mouse toward the end of pregnancy a dose of pitocin which ordinarily is ineffective causes a powerful contraction of the uterus. (9) Estrin acts as a "primer" for the action of the corpus luteum hormone (progestin, p. 750) and is apparently necessary also for the maintenance of the corpus luteum during pregnancy. When administered in large doses, however, it antagonizes the latter's action in bringing about the progestational changes in the uterine mucosa. (10) Prolonged dosage with the follicular hormone raises the blood calcium, especially in the fowl. (11) Estrin induces water retention, an increase in blood volume and of the water content of the muscles. Ovariectomy results in a loss of water and a diminished volume of blood which is restored to normal by estrin administration.

The origin and distribution of estrin (oestrin)

The elements of the ovary responsible for the production of estrin are not definitely known. Its presence in high concentration in liquor folliculi and the fact that follicular maturation coincides with the onset of estrus, point to the follicular cells (probably of the theca interna) as being the chief source. Yet these cells cannot be solely responsible, for Parkes showed that estrus continues at regular intervals after the follicles have been completely destroyed by X-rays; moreover, estrin can be extracted from the ovarian stroma alone. The interstitial cells in the latter situation may be one source of the hormone. One of the most remarkable features of estrin is its very wide distribution in animal tissues, though there is no evidence that in the non-pregnant state estrin is produced anywhere but in the ovary. It is found in the blood, muscles and urine of both pregnant and non-pregnant females, in the urine of adult males and in the testes, the testes and urine of stallions being among the richest known sources (Zondek). It is present in very high concentration in the urine of pregnant women after the first 2 or 3 months. In the late months around 300,000 or more international units are excreted daily. It is also obtainable in large amounts from the urines of pregnant mares and monkeys. The human placenta also contains large quantities of estrin which are believed to be actually manufactured by this organ, for women ovariectomized during the later months of pregnancy continue to excrete large amounts of the hormone in the urine. Estrin is present in the corpus luteum, in the fetal membrane and in amniotic fluid; it has been demonstrated in human chorionic vesicle containing an embryo 12.5 mm. in length.

Chemistry and terminology

Doisy and his colleagues and Butenand independently, isolated estrin in crystalline form from urine. Upon analysis it was found to have the empirical formula $C_{18}H_{22}O_2$ and to possess a ketone and a hydroxyl group. A second form of estrin containing one more molecule of water and having the formula $C_{18}H_{24}O_3$ was isolated from urine shortly afterwards by Marrian. The latter contains 3 hydroxyl groups but no ketone. It is less active than the previous form. Doisy gave the name *theelin* to the first of these forms; others speak of it as *ketohydroxyestrin* or *estrone*⁴ (oestrone).

⁴The advisory committee on nomenclature of endocrine principles appointed by the Council of Pharmacy and Chemistry of the American Medical Association.

the second form, called *theelol* by Doisy, is also referred to as *trihydroxyestrin* or *estriol* (oestriol); it is transformable to estrone by dehydration *in vacuo* with potassium bisulphate.

Estradiol (dihydroxyestrin, dihydrotheelin) ($C_{18}H_{24}O_2$) is a third crystalline compound which is first prepared in the laboratory by reduction of the ketone group in estrone to a hydroxyl group. There are three isomeric forms α , *iso* and β . The α -form possesses much the greater activity of the three. Since its artificial preparation α -estradiol has been isolated by MacCorquodale and his colleagues from sows' ovaries and by Doisy and his associates from the urine of pregnant women, it is now generally believed to be the true estrogenic hormone. Winterstein and his associates have isolated the beta-form from the urine

group in the 3 position in estradiol with benzoic acid gives a product possessing a more prolonged physiological action than the original compound.⁶ This substance—the *benzoate of estradiol*—is known commercially by various names. *Estradiol-dipropionate*, another laboratory product, has an even greater and more prolonged action.

Emmenin, isolated by Collip and his associates from human placenta is an ester (probably the glucuronide) of estriol. It is active by oral administration.

The term estrin is customarily employed as a general physiological designation for follicular hormone preparations regardless of their precise chemical constitution.

The structural formulae of four of the estrogenic compounds just described are as follows:

Ketohydroxyestrin,
(Theelin or estrone)

Trihydroxyestrin,
(Theelol or estriol)

Dihydroxyestrin or
estradiol

Benzoate of estradiol

of pregnant mares. Iso-estradiol is a synthetic compound and has not been obtained from a natural source. The replacement of the hydroxyl

association recommend the following chemical names, 3-hydroxy, 17-keto $\Delta^{1,3,5}$ -estratriene; 3, 16, 17-trihydroxy $\Delta^{1,3,5}$ -estratriene and 3, 17-dihydroxy $\Delta^{1,3,5}$ -estratriene, respectively, for estrone, estriol and estradiol. The numbering is shown in the following skeleton formula.

The presence in the blood during pregnancy of large amounts of estrin has always been something of a physiological puzzle, but some enlightenment has come through the discovery of Cohen and Marrian that estriol is excreted in the urine of pregnancy conjugated with glycuronic acid. This compound—the *glycuronide of estriol*—is physiologically inert, but is hydrolyzed, active estriol being freed, by the usual methods (involving acidification and heat) employed in isolating the hormone from urine. It was found, moreover, that the quantity of combined estriol in the urine of

This is probably due to the fact that the benzoate as compared with the other compounds is less readily attacked and inactivated by the liver.

women just before the onset of labor became reduced, whereas that in the active (free) state became greatly increased. The significance of these findings in respect to the activation of the birth mechanism is obvious (p. 734). The conjugation of estriol with glycuronic acid at once suggests a detoxicating process in the liver whereby the uterus is protected from the action of an excess of circulating estrogenic hormone.

Estrin and the hormones of the corpus luteum and testes belong to the class of sterols, being related chemically to the bile acids, to cholesterol and to calciferol. Starting with ergosterol, estrone was synthesized by Marker and his associates in 1936. Estrogenic substances have been obtained from a wide variety of sources other than animal tissues and fluids. Among some of these sources are petroleum, peat and lignite, yeast, rape seeds and pussy willows. Substances—benzanthracene compounds—with estrogenic properties and structural formulae suggestive of those given above have also been synthesized. The synthetic estrogenic compound, 4:4'-dihydroxy- α β diethylstilbene, known generally as *stilbestrol*, was introduced by Dodds and his associates in 1938 and has since come into clinical use. This substance exhibits an estrogenic potency between two and three times greater than that of estrone; its activity is reduced by only 50 per cent when given orally. Its formula is given below.

The relation between cancer production and estrogenic substances

Some of the estrogenic benzanthracene compounds are capable of causing cancer when painted on the skin, and coal tar which it will be recalled induces skin cancer is also estrogenic. These recent developments, associating carcinogenic and estrogenic effects and demonstrating the close chemical relationship between cancer-producing agents and the physiological substances mentioned, are highly suggestive. The production within the body (as a result of an abnormality in sterol metabolism of some material of the benzanthracene type which may play a rôle in the genesis of cancer, is a possibility which comes to mind. "The cell proliferation which characterizes the estrous state is in some respects reminiscent of the

early stages of malignant growth" (Cook and Dodds); so also is the development of the decidua tissue of early pregnancy which, as we shall see is dependent upon the hormone of the corpus luteum. The following suggestive observations may also be cited in this connection.

(a) Cori found that ovariectomy of mice belonging to a strain showing a very high susceptibility to mammary cancer caused a marked reduction in the incidence of the disease.

(b) Lacassagne produced mammary cancer in male mice, which ordinarily are not susceptible to the disease by the injection of large doses of an estrogenic hormone. This observer also states that differences exist between the estrous cycles of mice showing a high susceptibility to cancer and of those showing a low incidence of the disease: Loeb and his associates were unable, however to detect any characteristic feature of the cycles in the various strains of mice which could be definitely related to the occurrence of cancer.

(c) In women, cystic ovaries and apparently hyperovarian function, have been found in frequent association with an hypertrophied endometrium.

(d) In monkeys prolonged treatment with theelin has resulted in atypical growths of the epithelium of the uterine cervix.

Method of assay and standardization of estrogenic activity

It has been the practice to assay the activity of estrogenic preparations upon ovariectomized rats or mice, a unit being defined as the minimal quantity of the material required to induce estrus, as determined by the vaginal smear technique, in the test animal. A rat or a mouse unit has not, however, an absolute and definite value but shows wide discrepancies between different laboratories, owing to variability in the detail of the assay technique employed by individual workers. The Commission on Biological Standardization of the League of Nations has therefore defined a unit of estrogenic activity as the activity of 0.1 microgram (0.1 γ) of estrone. Three such *international units* are approximately equivalent to the original rat unit of activity as defined by Allen and Doisy. The dosage of estrone required to produce a physiological effect is related to the body weight. In order therefore to induce a response in a woman possessing no endogenous supply of the hormone something like 500,000 international units would be required.

THE HORMONE OF THE CORPUS LUTEUM

After the discharge of the ovum the cavity of the ruptured Graafian follicle becomes occupied by a clot of blood. The small body formed in this way is sometimes spoken of as the *corpus hemorrhagicum*. The clot is soon replaced by a mass

containing a yellow lipoid material (luteal cells). These are derived from the proliferation of the cells of the membrana granulosa (p. 745) of the theca interna.⁶ The follicle with its content of luteal cells constitutes the *corpus luteum* (fig. 302). The circumference of the follicle at this time has become more vascular and capillaries penetrate into the yellow cell-mass. The transformed follicle may now be looked upon as a temporary internal secreting organ. If fertilization of the ovum does not occur the life of the

FIG. 302. Section of corpus luteum showing luteal cells under high magnification (from Parkes, *The Internal Secretions of the Ovary*, by permission of Livingmans, Green & Co.).

corpus luteum is short. In the human it persists for about 10 days and then retrogresses. Its capillaries become obliterated, the luteal cells disintegrate and are replaced by fibrous tissue; nothing then remains of the follicle but a pale scar—the *corpus albicans*. On the other hand, if fertilization of the ovum results the corpus luteum continues to grow and in women attains a diameter of three-quarters of an inch or more by the middle of pregnancy. It then commences to shrink and is finally absorbed by about the seventh month.

Functions

The corpus luteum is essential to gestation. In some species (e.g., the rabbit and rat) it persists throughout pregnancy and abortion occurs if it is destroyed. In others (e.g., the human subject,

monkey, cat and guinea-pig) it is not indispensable after the earlier months of gestation (4 or 5 months in women). It is responsible for: (1) Changes in the uterine mucosa preparatory to the implantation of the ovum—pseudo-pregnancy of lower mammals and the premenstrual changes of primates. After implantation of the ovum the hormone of the corpus luteum is necessary for the development of the maternal placenta (decidua). (2) Growth of the mammary glands. (3) The suppression of estrus and ovulation.

The evidence for the foregoing is as follows: (a) Born observed that corpora lutea were not present in the ovaries of mammals which did not form a true placenta (monotremes). (b) Frankel, following up this hint, showed that if the corpora lutea were destroyed in pregnant rabbits abortion resulted.⁷ (c) If pregnant rabbits are injected toward the end of term with urine of pregnancy (p. 755), a fresh crop of corpora lutea appears and the gestation period is prolonged by several days; the fetuses become 50 per cent larger than normal and more mature (Snyder). A similar effect can be produced with the purified hormone of the corpus luteum. (d) Loeb discovered that stimulation of the uterine mucosa of the non-pregnant guinea-pig by means of a glass bead or a thread during the development of the corpora lutea resulted in the growth of a small mass of decidual tissue (deciduoma) at the point of stimulation. This effect, now known as the *Loeb reaction*, could not be obtained after the corpora lutea had been excised or during a phase in the estrous cycle when they were absent. Even transplanted uterine tissue responded to stimulation in a similar way if the ovary contained corpora lutea. Other observers have obtained corresponding results in the rat, rabbit and dog. Teel was able to produce deciduomata in the unmated rat by injections of a luteinizing extract (p. 753) of the anterior pituitary. The inference to be drawn from these experiments is, that the contact of the fertilized ovum with the endometrium is the natural stimulus which in the presence of a corpus luteum causes the formation of decidual tissue. (e) In the rabbit which does not ovulate except after copulation a corpus luteum does not form unless this act takes place, nor does pseudo-pregnancy occur. If, however, a corpus luteum is produced by the artificial rupture of a ripe follicle, or, as first shown

⁶ In most species, but probably not in all, the theca interna shares in the production of luteal cells.

⁷ In certain species, including the human, in which the corpus luteum degenerates in the later months of gestation ovariectomy at this time does not cause abortion.

by Ancel and Bouin, ovulation is induced by mating with a sterile (vasectomized) male, the characteristic endometrial changes of pseudo-pregnancy appear. (f) The mammary gland, or transplanted mammary tissue, shows increased growth during pregnancy and pseudo-pregnancy which has been correlated with the growth of the corpus luteum. Mammary growth ceases at the end of pseudo-pregnancy when the corpus luteum retrogresses and is slight or absent if the latter has been prevented from forming. In rabbits, artificial rupture of ripe follicles causes corpora lutea to form in some instances but not in others; only in the former does mammary growth occur. (g) The results of several experiments indicate that the corpus luteum inhibits follicular maturation and suppresses ovulation. It is well known that squeezing the corpora lutea from the cow's ovary by manipulation through the rectum hastens the onset of the next estrous period. Destruction of the corpus luteum in the guinea-pig acts similarly. Also, a greater quantity of the follicle-stimulating hormone (p. 754) of the anterior pituitary is required to induce ovulation in the presence of corpora lutea than in their absence. The function of the corpus luteum in suppressing ovulation provides against a second pregnancy being superimposed upon the first (superfetation).

The foregoing evidence for the function of the corpus luteum has been supplemented by the researches of Corner and Allen. These observers obtained an extract from the ovary of the pig which contained the active principle of the corpus luteum; this they called *progestin*. Injections of the principle into animals produces the following effects: (a) A perfect imitation of the progestational changes (pseudo-pregnancy) in the uterine mucosa of castrated adult rabbits.⁸ The uterus of the immature rabbit or of an adult animal which has been castrated some time previously, however, is unresponsive unless first "primed" by a previous course of estrin injections. In order to produce the typical progestational development of the uterine mucosa in the castrated monkey it is also necessary to administer both hormones; menstruation then occurs (Smith and Engle). Kaufmann showed similarly that in castrated women a premenstrual endometrium can be produced only by the administration of both the follicular and the corpus luteum hormones. The follicular hormone (estrin)

apparently initiates the progestational change causing vascularization of the mucosa and proliferation of the glandular elements, while the corpus luteum stimulates secretory activity and brings about the final alterations in the mucosa necessary for the implantation and nourishment of the fertilized ovum. Estrin also appears to be necessary for maintaining the growth of the corpus luteum of pregnancy and for the continued action of progestin upon the uterine mucosa. (b) Rabbits castrated early in pregnancy abort; injections of progestin enables them to be brought to full term. (c) Softening and relaxation of the pelvic ligaments and separation of the symphysis pubis of the guinea-pig; these effects imitate those occurring in pregnancy and are not obtained in the absence of the follicular hormone. (d) Inhibition of the uterine response to pituitrin (Knaus reaction). When the uterus of a rabbit which has been treated with progestin is excised it does not contract when pituitrin (even in large quantities) is added to the bath in which it is suspended; definite relaxation may result. The muscle will still, however, respond to adrenaline or quinine. The motility of the uterus of the intact animal is also suppressed by progestin. The change in reaction of the uterus of certain species to adrenaline (p. 687), from inhibition to excitation when pregnancy occurs is evidently due to the corpus luteum hormone, for a similar reversal of uterine behavior to adrenaline can be effected by progestin injections. (e) Estrin and progestin are antagonistic; according to Allen 675 rat units of estrin are neutralized by 3 units of progestin. The motility of the uterus of an infantile animal or of a castrated mature animal is inhibited by progestin; the uterus of a mature animal with intact ovaries is affected to a much less extent by the corpus luteum hormone.

The clinical uses of progestin are considered on p. 764.

Chemistry of progestin (progesterone)

The active principle of the corpus luteum has been obtained in crystalline form. Its structural formula is shown below (compare with the formula for estrone and estriol on page 749, with that for testosterone given on page 771, and with the crystalline compounds of the adrenal cortex (p. 693)). This crystalline product has been named *progesterone*, the older name *progestin* being reserved for the unpurified luteal principle contained in ordinary corpus luteum extracts. Progesterone occurs in two isomeric forms alpha- and beta-

⁸ A unit of progestin is defined as the minimum quantity that is required, when divided into 5 daily doses, to produce in a 4 kg. castrated rabbit uterine changes equivalent to those of the 3th day of pregnancy.

progesterone. They are about equal in physiological activity.

Starting with a sterol (stigmasterol) obtained from a soy bean Butenandt and his associates have recently succeeded in completing the later steps in the synthesis of progesterone. It has also been prepared by Butenandt from the conversion of pregnandiol.

Pregnandiol is a physiologically inert reduction product of progesterone isolated from the urine of a pregnant woman by Marrian in 1929. Its very close chemical relationship to progesterone is evident from the formula shown above; it is readily convertible to progesterone in the laboratory. Only minute quantities of progesterone itself are found in blood or urine. Similarly to estriol and other derivatives of testosterone (p. 771) pregnandiol is excreted in conjugation with glycuronic acid (Mell and Marrian). Injected progesterone appears in the urine as pregnandiol glycuronide. The occurrence in urine in different phases of the human sexual cycle has been investigated by Towne and his associates who found it present as *pregnandiol glycuronide* in the luteal phase of the menstrual cycle, but not in the follicular and intermenstrual phases. The excretion of pregnandiol commences a day or two after ovulation, reaching a maximum about a week before the onset of menstruation and ceasing 2 or 3 days before. During pregnancy much larger quantities appear in the urine, the greatest excretion being during the eighth and ninth months. In certain cases of spontaneous abortion the excretion is less than normal, a fact pointing to defective production of the corpus luteum hormone.

The international standard of potency used in the assay of progesterone preparations is defined as the progestational activity of 1 mgm. of the international standard preparation of progesterone.

The test animal is an adult female rabbit which has been mated and then castrated, or an immature female rabbit which has been primed for 5 days previously with estrin.

THE GONADOTROPIC (GONAD-STIMULATING) HORMONES OF THE ANTERIOR LOBE OF THE PITUITARY, GONADOTROPINS

Several observations in the past have pointed to the anterior pituitary as exerting an influence upon sexual development. The gradual atrophy and suppression of the sex functions in diseases of the anterior lobe in man (acromegaly, Fröhlich's syndrome) and the atrophy of the gonads after hypophysectomy in animals are among some of these observations (fig. 303).

FIG. 303. Effect of hypophysectomy upon the uterus. On right, uterus of normal rat; on left, that of an hypophysectomized rat. (After Van Dyke, *The Physiology and Pharmacology of the Pituitary Body*. Chicago Univ. Press.)

In the earlier experiments of Evans and associates with the saline growth-promoting extract of the anterior lobe of the pituitary (p. 724) it was

observed that the Graafian follicles became enlarged and filled with luteal cells (fig. 304). Usually, of course, corpora lutea form only after ovulation, but in these animals the estrous cycles

were suppressed, the ova remaining imprisoned within the luteinized follicles (atretic corpora lutea). The extract was later shown to depress the sex instincts of males and to reduce the weight of the testes. The male animals, however, remained fertile. Ovulation in hens was inhibited. These effects upon the sex processes were shown later to be independent of the growth hormone, for it was possible to separate the extract into two fractions, one having an effect upon growth, the other having the luteinizing effect just described.

FIG. 304. Ovary of adult mouse injected with alkaline extract of anterior lobe of pituitary. Large numbers of corpora lutea are present, and few follicles (from Parkes, *The Internal Secretions of the Ovary*, by permission of Longmans, Green & Co.).

It soon appeared that another sex hormone possessing a quite different effect was present in the anterior lobe. Smith and Engle found that when *fresh* mammalian anterior lobe tissue was transplanted daily into immature female rats or mice, estrus was precipitated and ovulation stimulated. The ovaries enlarged to 10 times the normal size (fig. 305), and developed a large number of follicles which ripened and discharged a "shower" of ova (superovulation). Corpora lutea formed within the rupture follicles, reached a small size and then retrogressed. The vagina, which is not a complete canal in the immature rat or mouse, opened, its epithelium changed from the columnar to the squamous type and the uterus enlarged from 5 to 10 times. Ovulation and estrus were also induced in adult sexually quiescent females. The testes, seminal vesicles and penis of immature males were stimulated to increased growth, and gonadal atrophy which follows hypophysectomy in either males or females was prevented by the anterior lobe transplants. Zondek and Aschheim

about the same time performed similar experiments in Germany upon immature female mice and obtained comparable results, the effects being evident within 100 hours. They pointed out that

FIG. 305. Showing effect of anterior pituitary upon ovaries. On left, below, ovaries of rat after twelve implantations of fresh rat pituitary gland; above, ovaries of litter mate control rat. (After Collip). On right, below, follicular maturation induced in immature rat on twenty-ninth day by eight daily implantations of fresh pituitary gland; above, ovary of litter mate control. (After Smith and Engle.)

the ovaries must be intact in order for estrus to occur. The essential action upon the female by this anterior lobe hormone is therefore to *stimulate follicular maturation and cause the liberation of estrin*. Estrus and its associated phenomena are secondary to the action of the latter hormone.

Aschheim and Zondek also showed that both effects of effect, luteinization on the one hand, and follicular maturation (ripening) on the other, could be produced in female mice by injections of the blood or urine of pregnant women (see pregnancy at below). Later work has shown that the follicle-stimulating principle may be obtained by

of the ovarian follicle, namely, the epithelium of the seminiferous tubules; large numbers of sex cells in various stages of development, including mature spermatozoa, are produced. The luteinizing principle, on the other hand, acts apparently upon the interstitial cells of the testes which are analogous to the thecal cells of the ovary (p. 745).

FIG. 306. Diagram summarizing the endocrine relationships of the anterior lobe of the pituitary

acid extraction of the anterior lobe. The follicle-stimulating hormone (whether in anterior pituitary or in pregnancy urine) was called *prolan A* and the luteinizing hormone *prolan B*. The gonadotropic principles are no longer referred to by these terms, but are known either as the *follicle-stimulating* and the *luteinizing hormones*, respectively, or as *gonadotropins I* and *II*.

The follicle-stimulating hormone also stimulates the tissue of the testes analogous to the granulosa

causing the liberation of the testicular hormone.* (See diagram, fig. 306.)

*Some workers believe that the gonadotropic functions of the pituitary are due to a single hormone and that the type of response obtained is dependent upon the dosage or upon the stage of the sexual cycle during which the treatment is given. The recent work of Wallen-Lawrence and of Fevold and Hisaw, and of a number of other workers have secured evidence strongly favoring the belief in two distinct hormones. They have obtained two nearly chemically pure preparations, the one having a follicle-stimulating action alone, the other causing luteinization.

The respective actions of the gonadotropic hormones of the anterior pituitary are tabulated below.

Follicle-stimulating hormone. ¹⁰	Ripening of follicles, superovulation, small corpora lutea.
	Production of estrin, phenomena of estrus.
	Proliferation of epithelium of the seminiferous tubules of the testes.
Luteinizing hormone:	Extensive luteinization, retained ova.
	Production of hormone of corpus luteum.
	Inhibition of estrin production, suppression of estrus. Stimulation of interstitial tissue of testes (p. 722).

These two hormones act synergically, the luteinizing principle being without effect unless preceded by the action of the follicle-stimulating hormone. The luteinizing principle is therefore inactive after hypophysectomy unless the animal has been primed with an estrogen.

It was shown by Bellerby that ovulation, which does not occur spontaneously in the rabbit, may be induced in this animal by injecting an acid extract of the anterior lobe. On the other hand, hypophysectomy of the rabbit one hour after copulation prevents ovulation, which normally occurs 10 to 12 hours after the act. Hypophysectomy performed later than one hour after copulation does not inhibit ovulation. These observations imply that rupture of the follicle and discharge of the ovum under ordinary circumstances is, in this animal, the result of a hormonal influence of some sort exerted by the pituitary. Liberation of the hormone responsible for the effect apparently occurs within one hour after copulation. Smith, however, does not believe that any specific "ovulation hormone" exists, but that ovulation is the result of a balance struck between the follicle-stimulating and the luteinizing hormones. Afferent impulses from the genital tract are apparently responsible, in part, for the liberation during coitus of the pituitary principle causing ovulation, but they are not essential, for Fee and Parks have shown that ovulation occurs after the vulva and vagina have been anesthetized. Sexual excitement resulting in an orgasm is capable alone (i.e., without coitus) of causing ovulation in the rabbit. That the influence upon the pituitary in this instance is of central origin is indicated by the observation that ovulation may be induced in the rabbit by electrical stimulation of the cerebrum or lumbosacral cord

(Marshall and Verney), or by the intravenous injection of the convulsant drug picrotoxin. Ovulation can also be induced by stimulation of the cervical sympathetic, the hypothalamus, the hypothalamo-hypophyseal tract of nerve fibers or of the pituitary itself.

The ovulation response is abolished with difficulty for impulses reaching the pituitary from many sources are capable of inducing it. Brooks found that it was not prevented after coitus though the sacral spinal cord, both sympathetic chains and the uterus, together with the proximal half of the vagina had been removed. Nor is it abolished by ablation of the neocortex and olfactory lobes. It no longer occurs, however, after section of the pituitary stalk. It is also abolished in animals whose hind limbs have been paralyzed by section of the lumbar spinal cord. Sexual excitement aroused by proprioceptive and tactile impulses from the limbs as the animal accommodates its posture during the act of copulation appears to be an indispensable factor in the response. The conclusion to be drawn from these various types of experiment is that though genital stimulations may elicit the response, they are not essential. On the other hand, the cooperation of the animal in the act of coitus and the associated sexual excitement appear to be necessary factors. If impulses reach the pituitary along the hypothalamo-hypophyseal tract of nerve fibers.

The following is a summary of the pituitary influence upon the sex mechanism. The follicle-stimulating principle initiates sexual activity. The ovaries or testes, stimulated by this anterior lobe hormone, bring about the psychic phenomena of puberty and of the estrous cycles of postpubertal life, as well as the physical changes in the accessory organs (vagina, uterus and seminiferous vesicles) characteristic of the sexually mature animal. It stimulates the development of the ova and granulosa cells of the follicles and, in the male, the epithelium of the seminiferous tubules. The luteinizing hormone depresses the first part of the ovarian cycle and encourages the second luteal phase, thereby bringing about the uterine changes associated with pseudo-pregnancy or with gestation. It acts specifically upon the cells of the theca and granulosa with the production of progesterone, or, in the case of the male, upon the interstitial cells of the testes with the production of male hormone.

The basophil cells (p. 722) are probably the source of the gonad-stimulating hormones; after castration the basophil elements of the anterior pituitary of the rat are increased in number and size ("castration cells"¹¹) while the gland's content

¹¹ These structures contain a large vacuole, the latter by pushing the nucleus toward the circumference of the cell gives it an appearance resembling that of a signet ring.

¹⁰ Smith suggests that since this principle stimulates the germinal tissue of both sexes it be called the *gametokinetic hormone*.

in gonadotropic principles increases. Moreover, when a castrated male rat and an hypophysectomized female are united parabiotically the female enters into continuous estrus and its ovaries show large numbers of follicles (superovulation). These results indicate that the relationship between the pituitary and the gonad is not one-sided but that the latter exerts, normally, a restraining influence upon the gonadotropic functions of the former. Such a relationship is supported by the converse observation, that continued treatment with estrin reduces the gonad-stimulating power of the anterior pituitary, the ovaries showing atrophic changes. The changes in the anterior lobe induced by estrin injections are, increased vascularity, reduction in number and ultimate disappearance of basophil and acidophil cells with proportionate increase in chromophobes. It is considered probable that the sequence of the two phases of the ovarian cycle is governed through the interplay of ovarian and pituitary hormones. Then, for example, as a result of follicular stimulation the estrin concentration in the blood reaches a certain level the liberation of the follicle-stimulating hormone of the anterior pituitary is suppressed and the discharge of luteinizing hormone brought about.

The Aschheim-Zondek test for pregnancy

The experiments of Aschheim and Zondek have led to the development of a practical test for pregnancy. After the injection of 2 cc. of urine of a pregnant woman (divided into 6 doses given over a 2-day period) into an immature male mouse 3 to 4 weeks old, the following ovarian changes are produced.

- (1) Ripening of follicles and estrus.
 - (2) Hemorrhages into some unruptured follicles, giving rise to "blood spots" (Blutpunkte) about the size of a pin's head.
 - (3) Luteinization of follicles in which the ova are retained—atretic corpora lutea.
- Effects (2) and (3) appear usually within 100 hours and permit a diagnosis of pregnancy to be made. Reaction (1) is not entirely specific since it occurs in conditions other than pregnancy, e.g., at the menopause (p. 762) and in new growths of the genital organs (see p. 758), especially teratoma. The test gives a correct result (positive or negative) in nearly 99 per cent of cases. A diagnosis of pregnancy as early as the first day after the first missed menstrual period

Estrin does not appear in large amounts in the urine until a much later date and small amounts are present

can be made by the use of this test.¹² The test fails in lower animals (e.g., rat, dog, cat, etc.) and the monkey, but is positive in the chimpanzee.

The test depends upon the presence of living placental (chorionic) tissue. Consequently a positive result is obtained when such abnormalities of gestation such as tubal pregnancy, hydatidiform mole or chorion-epithelioma exist. In the latter two conditions unusually large amounts of the gonadotropic principle are present in the urine. The test is also positive in threatened abortion but becomes negative when detachment and death of the ovum occur. Metastatic tumors of chorionepithelioma cause a positive reaction after removal of the uterus; the test may therefore prove invaluable as an aid in the diagnosis of the dissemination of this malignant disease. In the male, testicular tumors composed of malignant embryonal tissue (teratoma, epithelioma) also cause a positive test; such growths may result in the appearance of relatively enormous amounts of gonadotropic substance in the urine. Many cases of pituitary tumor give a positive test.

Friedman has modified the foregoing technique by substituting rabbits for mice as test animals. Since rabbits, ordinarily, ovulate only after sexual excitement, adult animals may be used for the test. This is a distinct advantage, as is also the fact that the ovarian reaction is developed much earlier—within from 16 to 36 hours (fig. 307). The animals must have been isolated from the males for at least three weeks prior to their use in order to ensure that natural ovulation has not occurred. Five to 10 cc. of pregnancy urine are given in a single intravenous injection. The percentage of correct diagnoses is about the same as when immature mice are employed.

The excretion of gonadotropic hormones in the urine

It has been assumed that the gonadotropic effects of pregnancy urine discovered by Aschheim and Zondek were due to the gonad-stimulating hormones of the pituitary; these, it was supposed, were elaborated in greater amounts during pregnancy than at other times, the excess being eliminated by the kidney. As a result of later work it is now generally agreed that the follicle-

in the urine of non-pregnant women. Aschheim states that the diagnosis of pregnancy by means of the urine is a very ancient practice. In an Egyptian papyrus some 3000 or 4000 years old it is directed that should a woman wish to know whether or not she is pregnant she should place some earth and barley in a vessel and add a little of her urine each day. Should the barley grow she is pregnant. It may be remarked that estrin, which as already mentioned, is present in high concentration in the urine after the first month or two of pregnancy, is a stimulant to plant growth.

stimulating and luteinizing effects of pregnancy urine are not due to the pituitary hormones but depend upon a *single* substance of a different nature. Pregnancy urine, for example, unlike anterior lobe transplants, will not stimulate follicular maturation or luteinization in the intact monkey nor in puppies or rats after hypophysectomy. Furthermore, reagents which are effective in extracting the urinary principle do not yield active extracts from the pituitary. The active principle in pregnancy urine is now referred to by some authors as *prolan*. This term tends, however, to perpetuate the confusion concerning

FIG. 307. Genital tract of mouse treated with urine of pregnancy. O, ovary; C.H., corpus hemorrhagicum; C.L., corpus luteum; F.T., Fallopian tube; U., uterus; V., vagina; (after Ettinger, Smith and McHenry).

the nature of the active principle in pregnancy urine. Collip and his associates have shown the latter to be identical with the gonadotropic substance of the placenta, and have named it the *anterior-pituitary-like substance* (A.P.L.) (see below). It is now more commonly spoken of as *chorionic gonadotropin*.

On the other hand, a hormone identical with the follicle-stimulating hormone of the pituitary and apparently elaborated by the latter is present in the urine of *castrated* animals and men, in the urine of pregnant mares and in the urine of women after the *menopause* or following *ovariectomy*. Its appearance in the urine may also be associated with *new growths* of the generative organs (both

benign and malignant but especially the latter), and with *raised intracranial pressure*. Occasionally it is found in the urine of normal men or of non-pregnant women before the menopause. This principle, unlike that in pregnancy urine, is effective when tested upon normal monkeys or hypophysectomized rats.

PLACENTAL HORMONES

The human placenta contains (a) the two forms of estrin;—*estrone* (ketohydroxyestrin or theelin, p. 749) and *estriol* (trihydroxyestrin or theelol); and (b) the *anterior-pituitary-like substance* or *chorionic gonadotropin* mentioned above. This ovary-stimulating principle has an action similar to but not identical with the gonadotropic principles of the anterior pituitary. Weisner extracted placental tissue with sulphosalicylic acid and obtained a gonadotropic substance which he believed consisted of two separate hormones—follicle-stimulating and luteinizing—identical with the gonadotropic hormones of the pituitary. He referred to them as rho I and rho II, terms which correspond to the names prolan A and prolan B used by Aschheim and Zondek. Collip, employing acetone as an extracting agent, obtained the ovary-stimulating principle but believed it to be a single hormone and showed that its physiological properties differed in certain respects from those of the pituitary hormones, hence the designation “anterior-pituitary-like.”

SUMMARY OF SOME OF THE MORE IMPORTANT OBSERVATIONS RELATING TO THE NATURE AND ORIGIN OF THE GONADOTROPIC PRINCIPLE OF PLACENTA AND PREGNANCY URINE, CHORIONIC GONADOTROPIN (URINARY PROLAN)

(1) When sexually immature rats, about 20 days old, are treated with A.P.L., prepared from the placenta or with extracts of pregnancy urine follicular maturation and estrus are induced; true corpora lutea are formed. The luteinizing effect predominates. The ovaries become enlarged, but the enlargement is somewhat less than that induced by anterior lobe extracts or implants. The ovarian effects of the urinary principle do not increase in proportion to the dosage, whereas those of pituitary transplants or extracts increase in direct relation to the amount of tissue transplanted or to the dose of extract (Evans and Simpson). A.P.L. prepared from the placenta or the gonadotropic principle in pregnancy urine causes marked development of the mammary glands in virgin rats. Enlargement of the prostate and seminal vesicles, and to a less extent of the testes of normal immature rats and of adult rats, is produced. The germinal epithelium

the testes is stimulated. The principle in pregnancy urine, unlike anterior lobe extracts, exerts no effect on the immature testes of birds.

(2) The A.P.L. principle, though obtainable in relatively large amounts from human placental tissue, is absent from the placentae of lower mammals; the gonadotropic principle disappears rather promptly from the urine shortly after parturition, and it is not found in the urine during pregnancy of any animal below the higher apes, though the pregnant mare secretes a gonadotropic principle of pituitary origin in the first month or so of gestation.

(3) In chorionepithelioma, a malignant tumor of placental (chorionic) tissue, and hydatidiform mole, a cystic degenerative disease of chorionic tissue, A.P.L. is present in large amounts in the pathological tissue and "prolan" is in high concentration in the urine. The gonadotropic hormone is found in high concentration in the chorionic villi of even very young embryos. It also appears in the urine of males suffering from tumors containing chorionic tissue.

(4) Tests of the gonad-stimulating properties of anterior pituitary tissue of women dying during pregnancy indicate that the gonadotropic principles in the pituitary during pregnancy are in very much lower concentration than in the pituitaries of non-pregnant women, and may even be absent. The diminished production of gonadotropic hormones by the pituitary during pregnancy is probably the result of the high concentration of estrin in the blood.

(5) Anterior lobe extracts will prevent ovarian atrophy in hypophysectomized animals, whereas the urinary principle exerts little or no protective action.

(6) Animals which have become resistant to the action of A.P.L. will still respond to anterior lobe extracts, and conversely those which have become resistant to the latter will respond to A.P.L.

The foregoing summary indicates that the A.P.L. substance of the placenta and the gonadotropic principle of pregnancy urine (prolan) are identical, i.e., the gonadotropic principle in the urine of pregnancy is derived, not from the pituitary but from the placental (chorionic) tissue. A possible function of the gonadotropin of the placenta is that it serves to supplement the action of the pituitary in maintaining the growth of the corpus luteum during pregnancy. The low concentration of gonadotropin in the pituitary of pregnancy conforms with such a possibility. According to this, if the placenta furnishes a hormone which, acting through the mediation of the ovary (corpus luteum), ensures its own physiological integrity, then a hormone liberated by the body of the embryo itself is not the factor which prevents regression of the corpus luteum as indicated by the results of an experiment of Collip, Selye and Thomson. They removed the embryos by Cae-

sarean section from rats between the ninth and thirteenth days of gestation, leaving the placentae intact. In a succeeding period of from eight to twelve days the corpora lutea remained unchanged, the placentae lived and the uterine mucosa between the placentae showed varying degrees of activity characteristic of this period of the pregnant state.

Is corpus luteum hormone formed by the placenta?

Though in some species, such as the rat, the corpus luteum persists to the end of pregnancy, in others, including the human, it commences to degenerate some weeks before term. In the rat and rabbit, abortion occurs if the corpora lutea are destroyed, whereas in the human and other species in which regression of the corpus luteum occurs, ovariectomy may be performed in the later part of pregnancy, though not during the earlier part, without abortion resulting. Even in the rat, though the embryos die after ovariectomy as a result of the uterus contracting upon them, and changes occur in the uterine mucosa, the placentae survive. Furthermore, if all the fetuses except one are removed from a pregnant rat, but *all* the placentae retained, removal of the ovaries after the middle of pregnancy does not cause abortion of the single fetus (Haterius). These facts have suggested the possibility that some tissue developed during the pregnant state—placenta or embryo—manufactures corpus luteum hormone. Some workers have prepared extracts from placental tissue which were capable of producing progestational changes in the uterus of the immature rabbit. The experimental results of Collip and his colleagues also give strong support to this view of placental function. They removed the *ovaries and embryos* from rats about the middle of pregnancy leaving the placentae undisturbed; the latter remained alive and apparently in a normal state during a subsequent period of from 5 to 9 days. The endometrium showed the normal gestational state; the mammary glands were well-developed, but did not secrete. From this and the experiment cited in the preceding section it is evident that the embryo does not elaborate a hormone which is concerned either indirectly through the luteal tissue of the ovary, or directly, with the maintenance of the placenta. Both these functions are probably performed by the placenta during the later weeks of pregnancy. Belief in the placental origin of the corpus luteum hormone is strengthened by the observation that the reduction product of progesterone, namely

pregnandiol, continues to be excreted in the urine following destruction of the corpus luteum in the later months of pregnancy.

THE MENSTRUAL CYCLE

UTERINE CHANGES

In primates (man, anthropoid apes and higher monkeys) the reproductive organs pass through a series of changes at periodic intervals. This constitutes the menstrual cycle. The most evident phenomenon of the cycle is the escape of blood from the vagina. The hemorrhage has its origin in the endometrium and is called *menstruation*.

Markee has followed the process of menstruation microscopically in patches of endometrium transplanted into the anterior chamber of the eyes of monkeys. Bleeding occurred from the transplanted tissue during menstruation, but preceded the appearance of blood in the vagina by about 3 hours. Estrin injections produced dilatation of the vessels of the graft. These observations emphasize the essentially endocrine nature of the uterine changes occurring during the menstrual cycle. In the human subject patches or tumors of endometrial tissue are sometimes found in extra-uterine situations, e.g., surface of the broad ligament or ovary; in the omentum, pelvic peritoneum or subcutaneous tissue of the vulva or perineum, or in the tissue in the neighborhood of a laparotomy scar. The ectopic tissue bleeds during menstruation and may give rise to attacks of severe pain. The condition is not very uncommon. It is referred to as *endometriosis*.

It is generally believed that rhythmical variations in the activity of the anterior pituitary are primarily responsible for the regular recurrence of the menstrual cycle, the ovary (through the discharge of estrin and progesterin) playing the rôle of intermediary. Menstruation is the most obvious event in the menstrual cycle and is customarily described as the first stage, but actually it is the culminating stage. It will therefore be placed last in the following division of the cycle. This order is also more convenient in correlating the ovarian cycle with the uterine changes.

(1) The *stage of repair and proliferation—follicular phase*. During this stage the epithelium of the endometrium which was shed during the menstrual flow is restored. The uterus enlarges as a result of the growth of its stroma; it becomes more vascular, its arteries become coiled, the epithelial lining hypertrophies and the glands show proliferative changes. Ovulation occurs at about the end of the proliferative stage which therefore

corresponds to pro-estrus of animals. The uterine changes are dependent upon the action of the follicular hormone (estrin).

(2) The *premenstrual or secretory stage—luteal phase*. This stage commences from 12 to 14 days before the first day of the menstrual flow. The uterine mucosa shows marked hypertrophy, glands become elongated and assume a coiled corkscrew form. The glandular secretion becomes greatly increased and more mucoid in character. This stage is dependent upon the action of the corpus luteum; it corresponds to pseudo-pregnancy of certain animals. Toward the end of the premenstrual stage the endometrium resembles the decidua of early pregnancy, typical decidua capsularis appearing in the uterine stroma. Toward the end of the follicular phase the vessels of the mucosa constrict. Swelling of the mammary glands and often mild psychic disturbances (irritability, nervousness, depression, etc.) occur. This stage may be absent from the menstrual cycle (p. 761).

(3) The *destructive stage or stage of menstruation*. This stage of menstruation lasts for about four days. The vasoconstriction toward the end of the follicular phase and the resulting ischemia of the endometrium lead to necrosis of the superficial layers; dilatation of the vessels then ensues accompanied by shedding of the necrosed tissue and bleeding from the denuded surface.

Menstrual blood as it appears externally is incoagulable. This is probably due to its containing a substance (fibrinolysin) which has destroyed the fibrin in the clots previously formed in the uterus or vagina.

OVARIAN CHANGES

The uterine changes are associated with just definite changes in the ovary. During the stage of proliferation of the endometrium the Graafian follicle is undergoing maturation. Ovulation occurs around the 15th day (13th to 17th) after the first day of the last menstruation, that is, about mid-way between two menstrual bleedings or "periods", and, as already mentioned, at about the end of the proliferative stage. Corner has recovered unfertilized ova at this time from the Fallopian tubes of monkeys, and Newell, Allen, Pratt and Bland, from the tubes of women. During the endometrial hyperplasia of the premenstrual stage the corpus luteum is developing. It reaches its maximal size at the end of this period if fertilization of the ovum does not occur, and its subsequent degeneration coincides with the onset of the menstrual flow.

of the menstrual flow (figs. 306 and 308). If fertilization and successful implantation of the ovum occur the corpus luteum continues to enlarge (p. 751). The excision of a recently formed corpus luteum is followed by menstruation or, if implantation of the ovum has occurred, by abortion.

Ovulation is accompanied by a sharp rise in electrical potential between the uterine cervix and the abdominal wall. This phenomenon was first demonstrated in the rabbit by Burr and his associates in 1935 and has since been fully confirmed by others. The potential change amounts to from 6 to 10 microvolts and lasts for about an hour. It is detected by means of electrodes placed in the situations mentioned, and connected to a sensitive potentiometer which activates a moving-cell galvanometer. The potential change can be recorded photographically. This method has been employed to ascertain the time of ovulation in women, the electrical change having been correlated with the presence of a recently ruptured follicle in the ovary.

Ovulation is also followed by the appearance of pregnandiol in the urine (p. 753). The detection of this derivative of progesterone is therefore taken as evidence of ovulation and fixes approximately the time of its occurrence.

It would seem that the menstrual rhythm once initiated is perpetuated automatically through the interaction of the pituitary and ovary. From the facts in hand it is possible to draw tentatively the following picture of the governing mechanism. Estrin increases in the body fluids, due to stimulation of the ovary by the follicle-stimulating hormone of the pituitary, but when the concentration of this ovarian hormone reaches a certain level it acts in turn to suppress the output of the follicle stimulating hormone; the concentration of estrin upon which the proliferative stage of menstruation depends is thus reduced. The hypophysis now releases its luteinizing principle which stimulates the development of the corpus luteum, but as the concentration of progesterone rises the production of the luteinizing principle is in turn suppressed, with the result that the integrity of the luteal tissue cannot be maintained. The concentration of estrin having by this time fallen to a low value, menstrual bleeding occurs and the secretion of follicle-stimulating hormone is then resumed—another cycle commences. There is evidence that the liberation of the gonadotropins of the pituitary is under the control of the hypothalamus.

A CONSIDERATION OF THE FACTORS CONCERNED IN THE PRODUCTION OF THE MENSTRUAL FLOW

Hartman's studies have shown beyond doubt that menstruation occurs without ovulation in the monkey, especially between mating seasons. Menstruation without ovulation also occasionally occurs in women. A corpus luteum of course is not formed in these instances and the typical premenstrual endometrial changes do not occur. It appears, therefore, that, though the breakdown of a premenstrual endometrium built up under the influence of the luteal hormone ordinarily coincides with the menstrual flow and is normally part of the mechanism, it is not an essential feature. On the other hand, estrin and the endometrial changes which it brings about are an indispensable part of the menstrual process.

Certain observations indicate that an important factor in the onset of menstruation is an abrupt fall in the estrin concentration of the blood. (a) In monkeys, and also in the human subject ovariectomy (which removes the source of estrin) is followed by uterine bleeding. This postoperative bleeding may be postponed by injections of estrin. (b) When a castrated monkey is given a series of injections of estrin, uterine bleeding occurs a few days after the cessation of the treatment but unless the injections are long continued no bleeding occurs during the course of the treatment. The same phenomenon has been observed in women. Progestin injections prevent the effect of the estrin treatment. (c) In non-pregnant women the maximum excretion of estrin occurs in the intermenstrual period, and the minimum just before or at the time of menstruation. (d) Injections of a gonadotropic extract of the anterior lobe of the pituitary into a monkey during the resting stage of the cycle causes bleeding a few days after the treatment has been discontinued. This result, since it cannot be produced after ovariectomy, is apparently due to estrin liberation and a rise followed by a fall in the estrin concentration of the blood. If the treatment with pituitary extract is followed by injections of estrin, menstruation is postponed until a week or so after the latter treatment has been discontinued.

To summarize: Menstruation can occur in the absence of ovulation; the premenstrual endometrium characteristic of the action of the luteal hormone is therefore not necessary for its occurrence. Stimulation of the endometrium by estrin is, however, absolutely essential, and a reduction

in the concentration of estrin in the blood appears to be the chief factor in the onset of the bleeding.

ATTEMPTS TO IDENTIFY MENSTRUAL BLEEDING WITH ONE OR OTHER PHASE OF THE ESTRUS CYCLE OF LOWER ANIMALS

The menstrual cycle of primates is homologous with the estrous cycles of animals (expressed in terms of lower animals, the human is polyestrous (p. 746)), but to what stage of the estrous cycle menstrual bleeding itself corresponds is a debatable question. In animals such as the dog and cow bleeding occurs in pro-estrus. This led Heap to suppose that menstruation was homologous with pro-estrous bleeding. But whereas the proliferative phase of the menstrual cycle corresponds apparently to pro-estrus in animals, menstruation does not occur until some 14 days after the termination of the proliferative phase (cf. fig. 308).

FIG. 308. Upper diagram, oestrous cycle. Lower, menstrual cycle. (After Corner.)

It has been mentioned that the premenstrual changes in the uterus resemble and are considered to correspond to those of pseudo-pregnancy in animals. Parkes and Bellerby have therefore suggested that menstruation is the homologue of the slight bleeding which occurs in some animals as the uterine mucosa breaks down at the end of pseudopregnancy. Color has been given to this theory by the fact that uterine bleeding promptly ensues after destruction of the corpus luteum. It has just been stated, however, that menstruation can occur in the absence of a luteal phase.

Marshall has suggested that menstruation corresponds to the hemorrhage at the end of pseudo-pregnancy and the bleeding of the pro-estrus period of the next cycle "telescoped" into one. The difficulty in correlating menstruation with pro-estrus bleeding has been mentioned. Furthermore, slight bleeding sometimes occurs in women at about the *time of ovulation* (intermenstrual period) which would be more comparable than menstruation with pro-estrus bleeding.

Another theory (*embryotrophic hypothesis*) postulates that menstruation is homologous with the extravasation of blood into the decidual tissues which occurs during implantation of the ovum and serves to nourish the embryo in the initial stages of its development. Occasionally the extravasated blood escapes into the uterine cavity and appears externally (the so-called *placental sign*); a similar hemorrhagic discharge occurs in animals in a certain percentage of pseudopregnancies. This theory is in harmony with the common observation that in women bleeding may occur shortly after conception (i.e., during implantation of the ovum which is indistinguishable from that of an ordinary menstrual period. The theory is attractive in that it interprets menstruation as the culminating event in the preparation of the uterus for the reception of a fertilized ovum, the growth of the corpus luteum and the premenstrual changes in the uterine mucosa constitute the earlier preparatory processes projected in anticipation of implantation.

It must be admitted that none of the foregoing views succeeds in harmonizing all the facts.

PUBERTY AND THE MENOPAUSE

The sexual life of the human female commences between the 12th and 14th years, when the first menstruation or *menarche* occurs. This period of sex awakening which is seen in animals and men of both sexes is referred to as *puberty*. The periods before and after are called *pre-pubertal* and *postpubertal*, respectively. The ovaries at this time show increased growth accompanied by the maturation of the Graafian follicles and the discharge of ova. The growth of the uterus is accelerated, the breasts enlarge and, in both girls and boys, hair appears up on the pubes and in the axillae. Deepening of the voice, enlargement of the genitalia (penis and testes), increased muscular development and growth of hair on the face are characteristic features of this period in boys. In both sexes, somatic growth, including the lungs, skeleton, kidneys and liver is accelerated.

Between the ages of 42 and 52 (average 47 years) the sexual processes come to an end. This time is spoken of as the menopause or climacteric. Menstruation ceases, retrogressive changes gradually supervene in the accessory organs of reproduction, e.g., atrophy of the uterus, shortening and narrowing of the vagina, loss of the pavement epithelium and its replacement by fibrous tissue and shrinkage of the mammary glands. The changes are the result of atrophic changes in the ovary—disappearance of the Graafian follicles together with a general fibrosis and shrinkage of the organ; similar changes in the uterus and vagina follow the removal of the ovaries in early

life—*artificial menopause*. Psychic phenomena, usually mild, are not infrequent accompaniments of the menopausal period. Occasionally serious mental disturbances, e.g., melancholia, appear at this time. Vasomotor disturbances, hot flushes, sweating, etc., are very common features of the climacteric. The effect of the natural menopause upon the sex libido varies in different subjects. In married women it shows little alteration as a rule. Estrin may be present in the blood and urine years after the onset of the menopause. The follicle-stimulating hormone of the pituitary appears in the urine after the cessation of the menses.

MENSTRUAL IRREGULARITIES

The non-occurrence of the menstrual periods in postpubertal life is called *amenorrhea*; except during pregnancy, when suppression of the menses is a physiological phenomenon, the failure of the menstrual cycles at any time between puberty and the menopause is abnormal. Amenorrhea may be either *primary* or *secondary*. In the former instance the menses have never occurred, in the latter they appeared but were subsequently suppressed. Primary amenorrhea is in many instances associated with arrested development of the reproductive organs. Scanty menstruation is termed *oligomenorrhea*. *Dysmenorrhea* is painful menstruation. *Menorrhagia* is the term applied to excessive loss of menstrual blood. *Metrorrhagia* is the loss of blood from the uterus in the intermenstrual periods. A large proportion of these menstrual irregularities, when unaccompanied by some gross disease (tumor, etc.) in the uterus, have an endocrine basis. Amenorrhea is frequently the result of ovarian hypofunction. Dysmenorrhea is the result of irregular and spasmodic contractions of the uterine muscle which probably have also in many cases a hormonal origin. In the past, excessive bleeding in the absence of some obvious uterine disease has been put down to inflammation of the uterine mucosa (endometritis). Before the important work of Hitschmann and Adler, who correlated the physiological changes in the endometrium with the stages of the ovarian cycle (p. 760), the normal premenstrual characters of the uterine mucosa were considered to be pathological—evidence of endometritis!

Shaw, from the study of a large series of irregular uterine bleedings unaccompanied by obvious disease of the uterus, came to the conclusion that only a very few could be attributed to inflamma-

tory changes in the endometrium but that the great majority were due to ovarian abnormalities. In one group (*metropathia hemorrhagica*) the bleeding was continuous, the uterine mucosa was thickened and showed dilated glands and areas of necrosis; the constant finding in the ovary was an unruptured cystic follicle. The bleeding is apparently due to the overproduction of follicular hormone and the prevention of the formation of a corpus luteum. According to Kaufmann the imbalance between these hormones causes the proliferative phase of the endometrium (p. 760) to become exaggerated, and prevents the onset of the secretory phase and the shedding of the mucosa as in normal menstruation. He describes the state of the endometrium as one of chronic cystic hyperplasia. This observer has produced a similar state of the endometrium in a castrated woman by the administration of large doses of follicular hormone.

In another group of cases of uterine bleeding reported by Shaw (*epimenorrhea*) the menstrual flow was prolonged, that is, the intermenstrual periods were much shortened; the ovarian cycles, due to premature rupture of the follicles, were also abbreviated, ovulation occurring with abnormal frequency.

In cases of irregular uterine bleeding of endocrine origin the ovarian disorders are possibly due in turn to disturbances of a functional nature of the anterior lobe of the pituitary. It is well known that gross diseases of this part of the pituitary (e.g., acromegaly, Simmonds disease, dystrophia adiposo-genitalis, pituitary basophilism, etc.) are associated with menstrual abnormalities. These, however, usually take the form of oligomenorrhea or amenorrhea. Amenorrhea also occurs as an accompaniment of hypothyroidism and as a symptom of several general diseases, notably anemia, tuberculosis and mental conditions; malnutrition is not infrequently a cause.

The *treatment* of menstrual disorders, supposedly of ovarian origin, by means of hormone preparations has been very disappointing, and this is perhaps to be expected until a clearer understanding of the underlying factors governing normal menstruation has been arrived at. Estradiol dipropionate or benzoate has been employed with some measure of success in secondary amenorrhea, especially if this has not been of long standing. Primary amenorrhea is not permanently benefited by the follicular hormone. Werner and Collin produced uterine bleeding in castrated women by the administration of estrin alone, but

the premenstrual type of endometrium was not produced. Treatment of primary amenorrhea with estrin and progestin together would appear to have a more rational basis and might be expected to give better results, for, though the progestational development of the uterine mucosa is not essential for menstruation (p. 761) this *does* occur in the normal subject. Yet even this mode of treatment is on the whole unsatisfactory. Kaufmann produced typical premenstrual endometrium in castrated women by the administration of the two ovarian hormones, but a total dose of over 1,000,000 international units of estrogenic principle (progynon) and 35 rabbit units of corpus luteum hormone were required to produce this effect. He also induced growth of the uterus and uterine bleeding in cases of primary amenorrhea associated with genital infantilism by the administration of enormous doses of estrin (up to 18,000,000 international units over a period of months) or of this hormone followed by injections of the corpus luteum principle. A premenstrual endometrium was not produced in these cases and the bleeding was therefore not considered to be normal menstruation. In cases of primary amenorrhea with well developed genitalia, a typical premenstrual endometrium followed by menstruation was induced by the administration of a total dose of from 1,000,000 to 1,500,000 international units of follicular hormone and from 35 to 50 rabbit units of corpus luteum hormone. In no case of primary amenorrhea of the first group and in only one case of the second, however, was a cure brought about, in the sense that normally recurring menstrual cycles occurred; after the course of treatment, the subjects in all the other instances relapsed into their previous amenorrheic condition. Such a result is to be expected, since the administration of ovarian hormones cannot correct the primary fault whether this be of ovarian or pituitary origin. In a number of cases of secondary amenorrhea, on the other hand, the spontaneous cyclic function of the uterus was restored by treatment with both hormones or with large doses of estrin alone.

Estriol, stilbestrol or emmenin, since they are more effective by oral administration than estrone, and therefore more convenient, are often used in its stead.

The greatest value of estrone or of the other estrogens is in the treatment of the nervous (psychic and vasomotor) disturbances of the menopause in which the estrin concentration in the blood and urine is frequently definitely subnormal.

Injections of estrogens in such instances relieve the vasomotor symptoms. Relatively small doses (200 international units daily) are required. Estrone has also been shown to be of definite value in the treatment of gonorrheal vulvovaginitis in children. Under its influence the vaginal epithelium undergoes cornification and, assuming the characteristics of the sexually mature woman, becomes more resistant to the disease. Estrone has also been employed with success in intractable cases of pruritis vulvae, and in certain ulcerative conditions of the vaginal mucosa.

Not until recently has an active preparation of progestin suitable for clinical use become available. Preparations previously on the market and claiming to contain the corpus luteum hormone were inert; this also applies to some of the preparations which are offered today. We have seen (p. 751) that the changes in the uterine mucosa which are essential to the fixation and nourishment of the fertilized ovum are dependent upon the hormone of the corpus luteum. Deficiency of the latter may be responsible for certain cases of sterility or of habitual abortion, and when such a cause is suspected, treatment with an active preparation (which must always be given by injection) is a rational procedure. The indication for the use of progestin in menstrual disorders is by no means clear cut. Its inhibitory effect upon uterine motility renders it a valuable agent in the treatment of dysmenorrhea; and its action in suppressing the menstrual flow has been the basis for its use in menorrhagia and metrorrhagia. Excellent results have been reported following its use in the latter conditions. Kaufmann found that up to 90 rabbit units of corpus luteum hormone were necessary in order to suppress the proliferative phase (p. 760) of the endometrium and bring on the secretory phase. Smaller doses, however, were frequently successful in terminating the bleeding. Progestin is of no value in the treatment of the symptoms of the menopause.

A.P.L. from pregnancy urine has also been advocated where treatment with corpus luteum hormone appeared to be indicated; the object being to stimulate luteinization and so to increase the subject's own supply of hormone. There is no evidence, however, that in the human subject A.P.L. causes luteinization; it has not this effect in the ape. Nevertheless, Campbell has reported success in the treatment of metropathia hemorrhagica with A.P.L. hormone. Novak and Hulse also report success in the treatment of menorrhagia with the anterior-pituitary-like principle. The

rationale of its action in these instances is obscure. Testosterone propionate (p. 771) has also been employed with satisfactory results.

The naso-genital relationship. A number of observations suggest a physiological relationship between the sex processes and the nose. In the first place the mucosa covering the conchae has a cavernous structure suggestive of the erectile tissue of the penis and clitoris, and olfactory stimuli and psychic aspects of sex are very closely associated. Nasal congestion, often accompanied by epistaxis, occurs regularly in many women at the time of the menses and in both sexes it is not unusual for nasal bleeding to occur at puberty. Sometimes the nasal hemorrhage in girls or women has seemed to replace menstruation which was coincidentally suppressed, and for this reason was termed erroneously "*vicarious menstruation*." Swelling and reddening of the nasal mucosa is a common finding in women during pregnancy and in monkeys during the estrous cycles. Stimulation of the interior of the nose has been reported to alter the periodicity of estrous cycles in rats, whereas excision of the conchae in young animals is said to result in hypoplasia of the sex organs. On the other hand, degenerative changes in the nasal mucosa have been observed as a sequence to castration, which could be reversed by estrin injections. Finally, pseudopregnancy has been induced in rats by the nasal application of a strong solution of silver nitrate and by removal of the sphenopalatine ganglion. Mortimer, Wright and Collip became interested in the nasogenital relationship from the study of a French Canadian family, all of whom (both parents and nine children) suffered from *atrophic rhinitis*. An examination of the cranial skiagrams of these subjects disclosed signs which were interpreted as indicative of pituitary abnormalities. The possibility of a causative connection between the pituitary (e.g., deficiency of gonadotropic principle) and the nasal disease suggested a trial of estrin for the treatment of the latter. The local application of the follicular hormone to the conchae of these patients and of a number of other subjects of atrophic rhinitis is stated to result in definite improvement.

THE DEVELOPMENT OF THE MAMMARY GLANDS AND THE SECRETION OF MILK

The rôles played by the ovaries and the anterior pituitary. Prolactin (synonyms: mammatropic, galactin, lactogenic hormone)

There are three phases in the development and activity of the mammary glands.

(a) The mammary growth which occurs in animals at puberty and at the commencement of subsequent estrus periods, is due, mainly, to estrin (p. 747). In monkeys, treatment with estrin will prevent the atrophy of the mammae

which otherwise follows castration. This ovarian hormone brings the mammary glands of the immature guinea pig to full development, promoting the growth of both the alveolo-lobular and duct systems as well as that of the epithelium of the nipple. In the monkey, growth of the alveolo-lobular system is also stimulated by estrin.

(b) The further enlargement of the mammary glands during pseudo-pregnancy and during the pregnant state is due to the growth of the corpus luteum. In most animals, although estrin can stimulate growth of the ducts, stroma and nipple, development of the alveolo-lobular system can not, as in the case of the guinea pig and monkey, be induced by the administration of the follicular hormone alone. It must be combined with or followed by progestin administration, which then induces growth of the alveolo-lobular system. The effect of the sex hormones upon mammary growth is enhanced by the administration of the thyroid hormone.

Undoubtedly, the development of the human mammae at puberty and their enlargement in the premenstrual periods and during gestation are also due to the influence of the ovarian hormones.

The researches of Turner and his colleagues, indicate that estrin and progestin exert their respective effects upon duct and alveolo-lobular growth, not directly, but through the intermediary of the pituitary. They postulate the existence of two pituitary hormones, *Mammogen I*, which induces duct growth and is liberated under the influence of estrin, and *Mammogen II*, which is controlled by progestin and stimulates the growth of the alveolo-lobular system. Estrin, it is thought also exerts a direct action upon the growth of the stroma of the mammae.

(c) The actual *secretion* of milk which occurs at the end of pregnancy is brought about through the pituitary. A lactogenic effect of anterior lobe extracts was demonstrated by Grueter and Stricker in 1929; and Corner in 1930 showed that injections of anterior lobe extract caused hypertrophy of mammary tissue and secretion of milk in ovariectomized virgin rabbits. The work of Riddell and his associates has demonstrated that the lactogenic effect is due to a separate hormone of the anterior hypophysis. These observers obtained extracts of the anterior lobe which had pronounced lactogenic effects but were practically free from thyrotropic, growth and gonadotropic principles. They named the hormone *prolactin*. It has since been obtained in crystalline form, and in the form of what appears, from electrophoretic and diffusion

studies, to be a pure protein. It is most probably a product of the acidophil cells.

Prolactin induces proliferation of the epithelium lining the crop glands of male and female pigeons and doves,¹² and increases the production of a caseous material, consisting of desquamated epithelial cells and known as "crop milk," with which the young are fed. The epithelium becomes heaped up into a number of layers, producing pronounced thickening of the mucosa, an effect which is strikingly evident even upon gross inspection. Great numbers of mitotic figures appear. The stimulant action upon epithelial hyperplasia is greatly magnified by the administration of colchicine, a drug which arrests mitosis in the metaphase stage. The maximum effect of the drug is manifested in from 6 to 8 hours and persists for a period of from 16 to 18 hours. The lactogenic hormone causes the mammary secretion in all species of mammals investigated. On the other hand, hypophysectomy suppresses milk secretion; and in the cat, though pregnancy is not terminated by hypophysectomy performed in the later months, lactation does not occur postpartum in the absence of the pituitary. Prolactin arouses the maternal instinct in virgin rats; Riddle and his associates have shown that in from 5 to 12 days after a series of injections the treated animals will care for young. It also induces broodiness in hens. Continued injections suppress the gonadotropic action of the hypophysis with consequent atrophy of the gonads. In pigeons prolactin manifests a growth effect upon the body as a whole, but especially upon the liver and intestines and probably upon the pancreas (splanchnomegaly).

That milk secretion in the human subject is also under the control of the anterior lobe is indicated by the fact that in acromegaly (p. 736) milk secretion may persist for an extraordinarily long time after childbirth (5 years in a case of Cushing's). It may also occur in male subjects of giantism (p. 737). These observations are most readily explained upon the assumption that in these pituitary abnormalities the overactivity of the anterior lobe causes, as well as an overproduction of growth hormone, a continuous secretion of prolactin, corticotropin and possibly other lactogenic principles. Prolactin preparations have been used clinically to increase the milk flow. Riddle and his associates report that in a series of

twenty-nine parturient women the daily milk secretion was increased in twenty-five of them from 50 to 400 grams in from three to nine days after treatment was instituted.

A CONSIDERATION OF FACTORS CONCERNED IN THE INITIATION OF THE MECHANISMS LEADING TO MILK SECRETION AT THE TERMINATION OF PREGNANCY

Though, as mentioned above, in most animals as well as in the human subject, mammary growth occurs during pregnancy, the flow of milk is not established until after the birth of the young and the expulsion of the placenta. Complete information concerning the factors which initiate the secretion after the birth of the child is not available; though the importance of prolactin in the secretion of milk has been proved, the influences determining its discharge from the pituitary and the part played by other hormones are, to a large extent, unknown. Experimental results relating to the factors concerned in the induction of lactation—both hormonal and nervous—will be briefly outlined.

HORMONAL. (1) When mammary growth is induced in the guinea-pig by the injection of estrin, secretion of milk occurs when the dosage of hormone is suddenly reduced. (2) Evans found that "prolan" (which induces luteinization of the ovary, p. 755) caused mammary development in virgin rats but not the secretion of milk. Collip and his colleagues reported that if in virgin rats the luteinized ovaries induced by the administration of A.P.L. were removed, the hypertrophied mammae secreted profusely. Removal of the pituitary, however, together with the ovaries prevented this result. (4) Lactation is inhibited by estrin injections or by measures which stimulate estrin liberation; it is also promptly suppressed by injections of A.P.L. hormone which stimulate the production of luteal tissue. (5) The mammary glands of women who have been ovariectomized during pregnancy do not secrete unless abortion occurs and the placentae are expelled. (6) When lactating cows become pregnant, milk production declines progressively throughout gestation and rises again abruptly after calving. (7) It has been reported that reduction in the estrin concentration of the blood of parturient women, may be induced by the administration of a diuretic such as theophyllin, stimulates milk secretion. These are among the observations which have suggested to many that in the intact animal lactation is held in abeyance by a high concentration in the blood of ovarian hormones (estrin).

¹² This action is employed as a means of assaying the potency of lactogenic extracts. In general terms a "bird unit" is the minimal quantity of extract required to induce a certain increase in weight of the crop glands of doves or pigeons.

gestin) and probably of placental hormones as well, but that with the fall in concentration of these hormones toward the end of pregnancy, or at partum the pituitary and the adrenal cortex (see below), now no longer restrained, exert their trophic action. Evans also explains the milk secretion which occasionally occurs in the child shortly after birth (witch's milk) on this basis. The blood of the fetus presumably contains ovarian hormones of the mother and the elimination of these after birth results in the liberation of prolactin from the infant's pituitary. The theory just outlined concerning the induction of lactation fails to explain the phenomenon in all species. In some cases, continued administration of estrin actually stimulates mammary secretion. The embryo itself does not apparently elaborate a hormone which stimulates mammary growth during pregnancy which inhibits the secretion of milk (see p. 9).

The lactogenic hormone apparently acts directly on mammary tissue, rather than through the intermediary of some other endocrine, for it is effective when injected into the mammary ducts. Nevertheless, the hormones of the thyroid and adrenal exert an influence upon lactation.

In milking cows, thyroidectomy causes a slight reduction in the quantity of milk and a more pronounced reduction in the yield of butter fat (Hraham). The administration of the thyroid principle or of iodinated casein increases the yield of milk as well as the fat content. These effects appear to be specific and not due simply to changes in metabolism, for raising the heat production 50 per cent or so above normal by means of dinitrophenol decreases both the volume and the butter fat of the milk. The effect of thyroidectomy is attributed, in part, to the removal of the parathyroids.

The adrenal cortex plays an essential part in milk secretion. Rats, adrenalectomized in the later months of gestation fail to produce the normal quantity of milk. The defect can be corrected by the administration of very large doses of cortin, but not by ordinary (maintenance) doses, or by a high salt diet. The effect of adrenalectomy upon mammary secretion may be to a large extent non-specific and results from the disturbance in mineral, water and carbohydrate metabolism, the drying up of milk production being an expression of the dehydrated state. Nevertheless, that the adrenal cortex plays a rôle in milk-production is shown by the fact that prolactin alone has no trophic action in hypophysectomized animals unless an extract of the adrenal cortex (or cortico-

tropin) is administered with it. This leads to the belief that normally the pituitary brings about mammary secretion by liberating the adenotropic hormone as well as prolactin. Of the adrenal principles, desoxycorticosterone has been found to be without lactogenic action, whereas, 17-hydroxy-11-corticosterone is effective. The importance of the adrenal cortex in lactation and certain recent observations with the glycotrophic factor of the pituitary, as well as the influence of the ovarian hormones have led many, especially Folly and Young, to doubt the specificity of prolactin. The hormonal control of lactation is probably more complex than has been thought and involves perhaps several hormones.

NERVOUS. Cannon and his associates have shown that sympathectomized animals (cats) are in most instances unable to suckle their young (p. 945); a small quantity of milk is secreted after the young are born but the secretion soon dries up; maternal instinct is abolished. It is also well known that after weaning the secretion of milk ceases; there are two possible causes for this: (a) removal of the stimulus to the nipples provided by the act of suckling, or (b) distension of the alveoli of the gland by accumulated milk. Selye has shown that it is the first rather than the second of these factors which is important. The main duct of the gland was ligated in rats but the young were allowed to suckle. The accumulation of milk caused marked distension of the alveoli but secretion was not inhibited. On the other hand, removal of the sucklings from the mother or excision of the nipples suppressed secretion. It is probable that the effect upon mammary secretion of stimulating the nipple is not a local one but is the result of afferent impulses reaching the pituitary. Such a mechanism would be analogous to that by which in certain animals a pituitary principle, discharged as a result of stimulation of the genital tract, induces ovulation (p. 756). The experiments of Selye, Collip and Thomson indicate that afferent impulses from the uterus in a similar manner exert an important influence upon lactation. In the rat and other animals emptying the uterus by Caesarean section before term is followed by milk secretion. Selye and his associates found that secretion did not occur, however, if the uterus after evacuation was maintained in a distended state by means of injections of melted paraffin wax (with a melting point a little above body temperature). They conclude that the emptying of the uterus and the consequent reduction in tension upon the uterine wall is a factor in the response of

the pituitary. The inhibitory effect, however, may not be specific but due to the illness of the animals after the operation (see Bradbury, 1941; Greene, 1941).

The experiments cited above indicate the importance of *afferent* nervous influences in milk secretion, presumably through the liberation of prolactin. On the other hand, the fact that secretion may continue after complete denervation of the glands and that mammary tissue transplanted into a pregnant animal secretes milk after the young are born provides clear evidence that *efferent* nerves are not essential to the secretory mechanism, the *immediate* excitation of the gland being mainly brought about, if not entirely, by the lactogenic hormone of the pituitary.

The posterior lobe does not exert a true lactogenic effect, that is, it does not stimulate the *secretion* of milk by the mammary cells, but through its action upon the smooth muscle of the alveoli and ducts, pituitrin causes the expression of milk from the gland and in this way may temporarily increase the *flow* of milk; but the daily milk production is not increased.

THE COMPOSITION OF MILK

The quantity of protein in cow's milk is about double that in human milk, but the sugar and fat contents are lower. The proteins of human milk are, however, of higher biological value. In cow's milk casein constitutes from 80 to 90 per cent of the total protein, and lactalbumin from 10 to 20 per cent, whereas in human milk from 30 to 40 per cent of the total protein is lactalbumin. According to Murlin, all the protein of mother's milk may be retained by the infant; a considerable proportion of the protein of cow's milk, on the other hand, is eliminated.

The greater part of the fat of milk (90%) consists of the glycerides of the higher fatty acids, myristic, palmitic, stearic and oleic. The glycerides of lower fatty acids, butyric, caproic, caprylic, etc., make up the balance. Milk also contains small amounts of free fatty acids and of the phospholipids, lecithin, kephalin, and cholesterol. Cow's milk contains a relatively high percentage of inorganic constituents, the concentration of calcium being some three times, that of potassium twice, of sodium four times and of phosphorus over five times greater than in human milk. The calcium of human milk is said to be better utilized than that of cow's milk.

Both cow's milk and human milk vary greatly both in composition and quantity. Many factors,

psychic, dietary, period of lactation, time of day (greater volume during the night), etc., exert their effects upon the quality and quantity of human milk; the output gradually increases up to a maximum of from 1000 to 3000 cc. at about the 25th week after childbirth and then gradually declines. Human milk of good quality contains all the elements essential for building body tissue and adequate amounts of vitamins A, B complex and C. Vitamins B₁ and D are in low concentration and may be present in inadequate amounts. The average compositions of cow's milk and a woman's milk of good quality are compared in table 72. Both the *quality* and *quantity* of the milk is influenced by diet. An ample diet tends to maintain both the quality and quantity of milk at a high level. Raising the protein in the diet tends to increase the total milk yield. A high fat diet increases the yield as well as the fat content of the milk. A carbohydrate-rich diet reduces both the yield and the quality of the milk.

TABLE 72

	TOTAL PROTEIN	CASEIN	LACTAL- BUMIN	SUGAR	FAT	ASH
	per cent	per cent	per cent	per cent	per cent	per cent
Cow's milk..	3.5	3.0	0.5	5	3.5	0.7
Human milk.....	1.5	1.1	0.4	7	4.0	0.2

Milk is a true secretion—the product of the cells composing the alveoli of the mammary gland. The alveoli are grouped into lobules and the lobules into lobes. The secretion is collected by a system of intra- and inter-lobular ducts and delivered to the exterior by a single main duct, the galactophore—which opens upon the surface of the nipple.

The sugar of milk—lactose—is formed from the glucose of the blood. The protein is synthesized from free amino-acids; the phospholipids (lecithin, cephalin) are derived from the phospholipids of the blood. As a result of such conversions the concentrations of glucose, amino-acids and phospholipids is somewhat lower in the blood of the mammary vein than in that of the mammary artery. The origin of milk fat is an unsettled question.

THE TESTES

Structure of the testes

The substance of the testes consists of a mass of coiled tubules—the *seminiferous tubules*—bound to

ether by a *stroma* of connective tissue. The latter carries the blood vessels and forms septa which divide the body of the organ into a number of pyramidal lobes. The seminiferous tubules in their convoluted portions are lined by several layers of epithelial cells derived originally from the germinal epithelium; these give rise in the mature animal to spermatozoa. The epithelial lining of the tubules is homologous with the stratum granulosa of the Graafian follicle in the ovary. The different cell layers represent stages in the maturation of the male sex cells. The youngest cells—the *spermatogonia*—lie against the basement membrane; the more mature cells toward the lumen of the tubule. The spermatogonia give rise to *spermatocytes* (primary and secondary). The secondary spermatocytes divide to form *spermatids* which are transformed without division into mature *spermatozoa*. Proliferation of the spermatogenic cells is stimulated by the follicle-stimulating hormone of the anterior pituitary (p. 753). Other smaller columnar-shaped cells are found lying among the spermatogonia with their somewhat conical bases, resting upon the basement membrane. These are the *cells of Sertoli*. They take no direct part in the formation of the spermatozoa, serving merely to support and nourish the germ cells. In the stroma, isolated groups of polyhydral epithelial-like cells are present—the *interstitial cells* or *cells of Leydig*. These contain lipid granules in their cytoplasm, and are stimulated, apparently by the luteinizing hormone of the anterior pituitary.

THE PHYSIOLOGY OF THE TESTIS—THE MALE HORMONE

The testis has two functions, namely, the production of germ-cells—*spermatogenic function*—and the elaboration of male hormone—*endocrine function*.

The results of castration and transplantation experiments, an account of which has been given at the beginning of this chapter (p. 743) leaves no doubt that the testis is a gland of internal secretion. The earlier attempts to extract the testicular hormone were unsuccessful. The chief cause of failure was probably that a reliable test object had not been devised. Among the first to attempt the preparation of an active material was the noted physiologist Brown-Séquard (1889) who administered testicular extracts to himself and thought that he acquired an increase of vigor and a greater capacity for work after the treatment. The idea that senescence was related to testicular atrophy and the consequent reduction or loss of the male hormone was revived a few years ago by Voronoff in France and Steinach in Germany. Transplantations of apes' testes into old men have been performed and claims have been made that

the grafted tissue lives and causes rejuvenation of the recipient. The evidence, however, is far from convincing. There is no reason to suppose that testicular atrophy has any causal relationship to old age phenomena. Indeed, it is well known that in the male the degenerative changes of the body incident to age usually far outstrip the decline in the sexual functions. In the female, on the other hand, regressive changes in the ovaries occur normally after a certain age, yet this event does not appear to hasten senile changes. Nor do eunuchs show premature senility. Furthermore, the bodily changes associated with declining years are degenerative and irreversible; it is therefore irrational to hope that rejuvenation can be brought about by a hormone liberated from grafted testicular tissue. Moreover, any hormone effect which might result from such a procedure would be only temporary, for the graft does not live (p. 744).

The spermatogenic function of the testis is affected adversely by several conditions, namely, repeated or prolonged exposure to X rays or to radium emanations, alcoholism, vitamin E or B₁ deficiency, close confinement (in certain animals) and an elevation in temperature of the testis tissue amounting to only a few degrees. In the developmental anomaly known as cryptorchidism the testis fails to descend into the scrotum; spermatogenesis does not occur in the undescended organ. The defect is due undoubtedly to the relatively high temperature of the abdominal cavity which is several degrees above that of the scrotum. Raising the testis of the normal adult animal from the scrotum and fixing it in the abdomen is followed within a few days by degeneration of the seminiferous tubules. But the latter are restored to their normal appearance and function if the testis is returned to the scrotum, provided that its stay in the abdomen has not been too long. It has also been found that exposure for 15 minutes or so to a temperature of 6°C. above the normal body temperature leads within 10 days or so to degeneration of the sperm-producing cells. The latter effect follows in the ram if the scrotum is enclosed in heat-insulating material, such as coverings of wool, so as to maintain the scrotal temperature a few degrees above the normal level. Though the human testis may suffer in febrile diseases as a result of the high temperature the loss of function is, as a rule, only temporary.

The internal secreting function of the testis is resistant to the conditions mentioned above. The undescended testis continues to secrete its

hormone, for castration effects are not seen in bilateral cryptorchidism; nor does exposure to the X rays or vitamin deficiency lead to a failure in the endocrine function of the gonads.

Ligation of the vas deferens has been stated by some (e.g., Steinach) to cause degeneration of the spermatogenic cells and an increase in hormone production. These claims have been conclusively disproved. Vasoligation, which has been advocated as a means of increasing the output of male hormone, is based upon error and is never justified for this purpose; it exerts no detectable effect either upon the sperm-producing cells or upon those of internal secretion.

(1) Growth of the comb, wattles and ear-lobs of the castrated cockerel (capon) and of the cock in hens (fig. 309).

(2) Inhibition of ovulation in hens.

(3) Prevention of the atrophy of the accessory male organs (seminal vesicles, prostate, Cowper glands) in the castrated guinea pig, rat or mouse (fig. 310); the maintenance of the pendulous fold of the scrotum, and restoration of the electric ejaculatory response in the hypophysectomized guinea pig.¹⁴

(4) Extension of the lives (as judged by motility of the spermatozoa in the epididymis of hypophysectomized guinea pigs. This fact suggests

FIG. 309. Showing the effect of testis hormone (from urine) upon the comb growth of capons. The birds in the upper photograph received daily injections over a period of 15 days. Lower photograph, untreated controls. (After Funk, Harrow and Lejwa.)

In many wild species the activity of the male reproductive organs is confined to a definite mating season. The changes occurring during this period of "rut," as it is called, are analogous to those which take place during the estrus periods of the female. The testes hypertrophy, spermatogenesis occurs, and sexual desire is aroused. The anterior pituitary exerts a governing influence upon the testes essentially similar to that which it exerts upon the female gonads (p. 756).

Pezard as early as 1911 produced comb growth in capons by the injection of a saline extract of testicular tissue. McGee in 1927 obtained an active lipoid extract of bull's testes. As a result of the subsequent studies of this worker and his associates and those of other investigators (Moore, Gallagher, Koch) the following effects of testicular extracts have been demonstrated.

that the testicular hormone normally performs an important function with respect to the life and motility of the male sex cells. The spermatozoa when formed are non-motile, becoming so only upon reaching the epididymis where, apparently they are acted upon by the male hormone. Spermatogenesis in the immature (33 days old) rat can also be induced by injections of testosterone.

(5) Reduction in the size of the testes as a result of injury to the seminiferous tubules by repeated injections. This effect, as in the case of estrus upon the ovary (p. 748), is probably exerted through the hypophysis.

¹⁴ Passing an alternating electric current (30 volts) through the head of a normal anesthetized guinea-pig causes an ejaculatory reflex and the discharge of secretions from the vas deferens, seminal vesicles and prostate. This response was discovered by Batelli in 1922; it is abolished after castration.

(6) Restoration to normal of the "castration cells" of the anterior pituitary, (p. 756).

(7) Masculinization of female rat fetuses following repeated injections during pregnancy; hyperrophy of the uterus and reduction in the size of the ovaries of newly-born rats.

The testis hormone belongs to the class of sterols, being closely related chemically to the female sex hormones, to cholesterol, the bile salts, etc. (see p. 457). It has been obtained in crystal-

that of androsterone. The urinary androgens are apparently excreted as physiologically inactive glucuronides (see p. 749). Acid hydrolysis of the latter in the process of extraction liberates the active principles. *Androstenedione*, $C_{19}H_{26}O_2$, and *androstenediol*, $C_{19}H_{30}O_2$, are laboratory products, the former having been prepared from androsterone, the latter from dehydroandrosterone. Esterification of testosterone, as demonstrated by Parkes, greatly increases and prolongs its action,

FIG. 310. Effect of castration and testis hormone on epithelium of seminal vesicles. (Moore, Hughes and Gallagher.) 1, cells from normal animal, showing secretion granules; 2, cells from twenty-day castrate; 3, cells from twenty-day castrate treated with male hormone.

ine form from testicular tissue; this product, which is regarded the true male hormone, has been named *testosterone*. Butenandt isolated a crystal-

testosterone acetate and propionate, especially the latter, being several times more effective than the free hormone.

Testosterone

Androsterone

Dehydroandrosterone

line androgenic compound from urine. This is much less active (from $\frac{1}{4}$ to $\frac{1}{10}$) than testosterone and differs from the latter in chemical structure as shown in the formulae given below; it is called *androsterone*. Both testosterone and androsterone have been prepared from cholesterol by Ruzicka and his colleagues.

A second androgenic compound, *dehydroandrosterone*, is present in urine; its potency is about half

Testosterone is most effective when administered by injection; it is also effective percutaneously (by inunction) and by mouth but several times the injected dose is required. Androgenic substances (androgens) first make their appearance in male urine at the time of puberty or somewhat earlier. Androgens, surprisingly enough, are also present in female urine in amounts not greatly less ($\frac{1}{4}$) than in male urine and, as already mentioned, estrin

(probably estrone) is excreted by the male.¹⁵ The androgen/estrogen ratio (i.e., the number of international androgenic units excreted per day over the estrogenic activity in micrograms of excreted estrone per day) is from two to five times higher in males than in females (see Gallagher and colleagues). The main source of the androgens in female urine is the ovary, for ovaries grafted into the ears of castrated male rats maintain the seminal vesicles and prostate in a normal state (Hill); yet excretion is not entirely abolished by ovariectomy. It must be borne in mind that the male and female hormones are closely similar in chemical structure; estradiol can be converted to testosterone by dehydrogenation, and testosterone injected into a male is excreted partly as androgen and partly as estrogen. Furthermore, progesterone in large doses is capable of androgenic effects (the maintenance in castrates of spermatogenesis and enlargement of the prostate). The adrenal cortex probably furnishes a proportion of the androgens and estrogens found in normal urine, and all of those excreted after castration or ovariectomy. The excretion of both androgens and estrogens is reduced to around one-third of the normal in eunuchoidism and to small amounts after castration (human). In adrenal virilism (p. 698) the excretion of androgens may be, though not always, considerably increased.

Several methods have been proposed for assaying the potency of testicular preparations. Gallagher and Koch use the comb-growth test. They define a unit of testes hormone as the amount of extract which when injected daily for 5 days yields an average of 5 mm. increase in size (length plus height) of the combs of at least 50 per cent of a group of brown leghorn capons.

In animals which show a rutting season the male hormone is secreted intermittently, in others, e.g., the rat and guinea pig, and in man, the secretion is continuous. The elements of the testis which elaborate the hormone are not known with certainty, though it is generally believed that the interstitial cells of Leydig serve this function. The following is a summary of the evidence usually cited in support of this view.

(a) Treatment of the testes with mild doses of X-rays, or tying the vas deferens but leaving the spermatic vessels intact, results in atrophy of the

seminiferous epithelium; the interstitial cells remain unaffected and castration effects do not develop.

(b) When the testes are removed and grafted elsewhere in the body the seminiferous tubules degenerate but not the interstitial cells; castration effects are absent.

(c) When the testicles do not descend to the scrotum (cryptorchidism), the seminiferous tubules degenerate (probably as a result of the high abdominal temperature) while the interstitial cells are apparently unaffected. Subjects with undescended testes are sterile but are sexually normal otherwise.

This evidence for the belief that the cells of Leydig furnish the male hormone is not absolutely conclusive, for it cannot be stated with certainty that under any of the conditions mentioned the spermatogenic cells and the cells of Sertoli have not completely degenerated. Furthermore, in certain birds the cells of the seminiferous tubules show marked hyperplasia during the mating season, whereas the interstitial cells at this time become less prominent than they were previously.

Hypogonadism and hypergonadism in the male

Tumors of the testis in young boys may result in precocious development of the secondary sex characters—growth of hair upon the pubis, in the axillae and on the face, deepening of the voice and enlargement of the penis. These effects are evidently due to hypersecretion of the male hormone, they tend to subside after excision of the tumor. Hypergenitalism with closely similar features occurs as a result of hyperfunctioning of the adrenal cortex (p. 698). Failure of development of the accessory male sex organs and of the secondary sexual characters, a condition referred to as *hypogonadism* or *eunuchoidism*, is in most cases due primarily to a pituitary disorder. Deficiency of the gonadotropic hormone of the pituitary leads to atrophic changes in the testes, which may be greatly reduced in size, and to the suppression of their internal secretion. In other instances of eunuchoidism the testes are the primary site of disease, e.g., destructive new growths, mumps, typhoid fever, syphilis, etc. Testicular atrophy occasionally results from prolonged anorexia, severe inanition or of vitamin B₁ deficiency. Hypofunctioning of the testes may commence at any time during postpuberal life as a result of pituitary disease or of any of the conditions just mentioned. In the *deferred type of eunuchoidism* regressive changes, though usually of mild degree, in the accessory organs of sex and in the secondary sex characters may result. In many instances of hypogonadism in females as well as in males the excretion of gonadotropins in the urine is increased.

¹⁵ In some instances a part of the androgenic activity of urine, especially in cases of virilism (p. 698) may be due to the presence of *adrenosterone*, the androgen found in the adrenal cortex.

The sex hormones in relation to prostatic disease

The theory has been advanced that excessive production of male hormone is a factor in prostatic hypertrophy, it is an unquestionable fact that the male hormone (testosterone) stimulates prostatic growth. Nevertheless, it is improbable that hypersecretion by the interstitial cells is a factor in the causation of prostatic hypertrophy in man; secretion of the male hormone tends to decrease rather than to increase with advancing years.

It has been mentioned that estrin is excreted in the urine of the male and can be isolated from testicular tissue; it has also been shown by Zuckerman and Parkes that injections of estrin into monkeys causes prostatic hypertrophy, fibromuscular overgrowth of the whole prostate together with epithelial stratification and distension of the uterus masculinus. Such effects can be counteracted by injections of male hormone. These facts, taken in conjunction with the observation that the concentration of the male hormone in the urine of elderly men may be reduced while the excretion of estrin remains unchanged, have led some (de Jongh, Laqueur) to a conclusion as to the cause of prostatic hypertrophy in man which is opposed to that outlined above. They believe that an important factor leading to enlargement of the prostate is an imbalance between the male and female hormones—a *diminished* production of the former and, in consequence, a relative *excess* of the latter. In support of this hypothesis de Jongh states that injections of the male hormone in cases of prostatic enlargement prevents further hypertrophy and may actually cause shrinkage of the organ. Moreover, R. A. Moore and his associates observed that prostatic tissue of the rabbit transplanted into the anterior chamber of the eye showed a greater growth response to estrin than to male hormone administration. Nevertheless, observations opposed to this theory can be cited, e.g., the absence of excessive amounts of estrin in the blood or urine of subjects of prostatic hypertrophy, and the fact that estrin injections do not, apparently, aggravate the condition. The whole question of the causative factors in prostatic hypertrophy is rife with speculation and beset with contradictory observations and opinions. Established facts are few and difficult to obtain.

The epithelial cells of a prostatic adenocarcinoma are dependent for their growth and activity, as is the normal epithelium of the prostate, upon the male hormone. It is upon this basis that castration has been employed in the treatment

of prostatic cancer, the malignant growth, in many cases, undergoing regression after operation. Since androgen activity is antagonized or neutralized by estrogens, inhibition of the cancerous growth can also be induced by the administration of estrogenic material, e.g., stilbestrol.

The hormonal treatment of male sex disorders

The testis hormone, in accordance with the principle of hormone action in general (p. 670) does not stimulate the interstitial cells of the testes. Though highly successful results, of a temporary nature at least, have been reported following the use of the male hormone in underdevelopment or regression of the accessory sex organs, it is too early to attempt any real appraisal of its ultimate therapeutic value in these conditions.

The gonadotropic principle derived from pregnancy urine (p. 755) has been employed to stimulate spermatogenesis in an undeveloped testis or to restore the normal spermatogenic function which had been suppressed as a result of disease. Sterility in man is said to have been cured by this means; spermatozoa which before treatment were few and non-motile have, according to report, been increased in number and rendered actively motile after a series of injections of the anterior-pituitary-like hormone. Notable success has followed the use of the gonadotropic hormone of pregnancy urine in cryptorchidism, descent of the testes being induced. It has also been employed in various types of hypogonadism. The gonadotropic principle of the pituitary itself would be expected to give the best results but so far a reliable commercial preparation of this hormone has not been available.

THE THYMUS

Structure

The thymus arises from the third branchial cleft (and sometimes the fourth) on either side, each anlage going to form one of the lobes of the thymus. Each thymic lobe is composed of a number of lobules in which an outer portion or *cortex* and a central portion or *medulla* may be distinguished. The *cortex* resembles lymphoid tissue, being constituted of masses of small round cells—*thymocytes*—identical in appearance with small lymphocytes. The epithelial elements of the embryonic structure is almost entirely replaced during development by the ingrowth of these lymphoid cells from the surrounding mesenchyme. A small number of elongated reticular cells are seen scattered among the lymphoid elements. The *medulla* also contains lymphocytes but in fewer numbers; the reticular cells are thus

shown up more prominently and are seen to form a definite reticular stroma. Scattered throughout the medulla are round or oval elements from 30 to 100 microns in diameter known as *Hassal's corpuscles*. These bodies, which are the remnants of the original epithelial elements, are composed of cells arranged concentrically; they stain with acid dyes and therefore stand out conspicuously against the surrounding basophilic substance.

Possible Functions

The thymus of the infant is of relatively large size but during later childhood its weight in relation to body weight gradually decreases; little change in its absolute weight (25 to 40 grams) occurs; after the age of puberty a definite involutionary process commences. Though the involutionary changes, which consist of a reduction in the number of lymphocytes and reticular cells and their replacement by fat, are most marked during adolescence, they continue slowly throughout the rest of life. The corpuscles of Hassall disappear more slowly than the other elements.

It is admitted by most observers that the thymus serves a lymphopoietic function. Beyond this little is definitely known concerning its physiological rôle. It is enlarged in exophthalmic goiter, myasthenia gravis, adrenal insufficiency and in certain leukemic states. Thymic enlargement has also been considered to be a feature of the so-called *status thymico-lymphaticus*, a condition believed to consist of hypoplasia of the vascular system, a general increase in lymphoid tissue throughout the body, and a tendency to fatal syncope. Infants and young children who have died suddenly as a result of some trifling shock or during anesthesia have been thought to be subjects of this disease; it has been thought that enlargement of the thymus was in some way responsible. An investigation carried out recently by Turnbull and Young for the Medical Research Committee of Great Britain has failed to substantiate this belief. In the post-mortem examination of a number of children's bodies no relationship between the size of the thymus and vascular hypoplasia to the amount of lymphoid tissue in other parts of the body was found. In subjects dying suddenly as a result of shock or during anesthesia the thymus was not larger than in subjects dying from other causes. These investigators conclude that there is "no evidence that so-called *status thymico-lymphaticus* has any existence as a pathological entity." The possibility has been suggested that such cases of sudden death in infants are due to failure in function of the adrenal cortex.

The great body of experimental work which has been carried out in the past in efforts to elucidate the functions of the thymus have yielded little evidence which would enable it to be classified definitely among the glands of internal secretion. There is certainly no feature of its minute structure which suggests a glandular function. Numerous investigators, nevertheless, have claimed that their findings pointed to the thymus as playing an endocrine rôle. The problem has been studied both by the use of extracts of thymic tissue and by observing the effects of extirpation of the organ. Among the functions claimed for the thymus as a result of these two lines of investigation are, the regulation of calcium metabolism and the control of skeletal growth. Defective mineralization of the bones has been described

FIG. 311. At right, control rat 14 days old; at left, third generation thymus test rat 15 days old. (After Rowntree, Clark and Hanson.)

following thymectomy; others believe that the operation results in dwarfing. Gudernatsch found that feeding thymus tissue to tadpoles stimulated their growth but delayed metamorphosis. Thymectomy in pullets and pigeons is said to result in their laying eggs with uncalcified shells. Asch and his colleagues claim that thymic extracts contain a growth-promoting principle which they have named "thymocrescin," this material is said to stimulate the sex organs. The fact that thymic involution is delayed by castration but is most pronounced at the age of puberty has led several observers to the belief that the thymus is concerned in some way with sexual development.

Much of the earlier work on the thymus is very difficult to appraise, owing to the indecisive nature of the data or to the conflict between the results obtained by different workers in the field.

Anderson has made the interesting observation that rats exercised to the point of exhaustion show hypertrophy of the thymus and hypertrophy of the renal cortex. Selye has described similar changes following a variety of injurious agencies part of what he has termed the "alarm reaction."

Within more recent years Rowntree, Clarke and Anderson have reported spectacular effects following the intraperitoneal injection of thymus extract in successive generations of rats. Rats from the third to the seventh generation (F_3 to F_6) of a strain which had been treated in the preceding generations with thymus extract were described as showing an extraordinary acceleration of growth and development (fig. 311). The eyes and ears opened much earlier than usual and the body became covered with fur much sooner in the treated strain than in the controls. The treated animals increased rapidly in weight but, though the adult size was reached prematurely, they did not ultimately become larger than the controls. In males the testes descended at an unusually early age and fertility was increased. In the females showed pronounced sexual precocity, the vagina opening by the 20th day; litters were cast within from 40 to 45 days after birth. After the treatment had been continued for several generations its omission for one generation nullified the effects which otherwise would have appeared in the offspring of that generation. Thymectomy in several generations of parents resulted in retardation of growth and in the rate of development of the young. The effects upon the young of thymectomy of the parents were prevented by the treatment of the latter with extract. There has been no decisive confirmation of these results from other laboratories, and proof that the thymus possesses an endocrine function has not been obtained.

THE PINEAL BODY OR EPIPHYSIS

Origin and structure

This is a small gland-like structure (about 10 mm. long in man) somewhat resembling a pine-cone (pineal shape), situated just beneath the splenium of the corpus callosum and resting in the groove between the superior colliculi. The pineal arises as a diverticulum from the roof of the third ventricle. The cavity of the original pouch eventually disappears, the fully developed gland being composed of a solid mass of cells. The histological features of the pineal are very diverse, the picture varying from species to species and with age. In general however, it may be said to have a pseudo-lobular structure, the cells being arranged in masses or lobules surrounded by a highly vascular connective tissue. The cells composing these masses are of two main types. (a) *Parenchyma cells*. These are large cells with pale nuclei surrounded by a reticulated protoplasm

containing oxyphil granules. Each cell has numerous long processes, many of which end in club-like swellings. (b) *Neuroglial cells*. These are scattered among the parenchyma cells and, as a rule, are not numerous. Their long fibrous processes interlace with one another to form a framework for the lobule.

Involutionary changes are said to commence in the human pineal body about the seventh year. After this age laminated bodies composed of phosphates and carbonates of calcium and magnesium—the so-called "brain sand"—make their appearance.

Functions

The structure of the pineal has suggested an endocrine function but there is really little definite evidence from which such a conclusion may be drawn. In children destruction of this gland by disease has been followed in some cases by precocious sexual, skeletal and mental development, together with adiposity. However, in other instances of destructive disease of the gland no such developmental abnormalities have been observed. Dandy removed the pineal from puppies and found no sexual or somatic abnormality. The well-being of the animals was not affected. Horrax however, thought that the testes of guinea-pigs, rats and chickens showed precocious development after pinealectomy. He also reports a case of precocious sexual, mental and bodily development of a young boy in whom a pineal tumor was found at autopsy. Foa also reported hypertrophy of the comb and testes and the precocious development of sexual instincts in young male fowls after pinealectomy. These observations would suggest that the pineal normally exerts an inhibitory influence upon sexual development but Foa's results are far from being decisive. Recently Anderson and Wolf in a careful research found no effect of pinealectomy in young rats. The body growth, time of puberty or weights of the pituitary, thyroid, adrenal or thymus of either sex were not significantly influenced by the operation; no increase in the weight of the testes was noted and the estrus cycles occurred normally. McCord and Allen state that pineal feeding causes contraction of the melanophores of tadpoles.

It is clear from the equivocal or negative nature of the experimental results which have just been sketched that the function of the pineal, if indeed it possesses any physiological significance at all, is a riddle which so far has gone unanswered. The recent work of Rowntree and his colleagues suggests the possibility that the pineal like the thymus exerts an influence upon racial development. They report that pineal extract administered to parent rats in successive generations, results in retardation of growth but accelerated development of the young—"precocious dwarfism." Final judgment of this work must be reserved until the findings are confirmed.

SECTION VIII. THE NERVOUS SYSTEM

CHAPTER LXIII

INTRODUCTORY: THE PHYSIOLOGICAL PROPERTIES OF NERVE

THE STRUCTURE OF NERVOUS TISSUE

The structural unit of the nervous system is the *nerve cell* or *neuron*. Other elements—*neuroglial cells*—lying among the nerve cells serve as a supporting framework.

The neuroglia probably serves also as insulating material between neighboring neurons, preventing changes in electrical potential from spreading from one nerve fiber to another. The neuroglial cells possess numerous branching processes which interlace with one another to form a dense felt-work between the neurons (fig. 312). These interstitial cells of the central nervous system are present in both the gray and white matter; they vary greatly in size and shape and their processes in number and arrangement. Upon a basis of these differences they have been classified into three main types—*astrocytes*, *microglia* and *oligodendroglia*. The microglia are considered by most observers to be reticulo-endothelial elements (p. 78). They are migratory and phagocytic, wandering into the nervous tissue from the meninges along the blood vessels. In inflammatory processes involving the central nervous system these cells are increased in number. The oligodendroglia are believed to play a part in the formation of the myelin material which sheathes the nerve fibers. Though neurons do not multiply in the adult body and when destroyed are not replaced, certain neuroglial cells possess the power of active proliferation. This may occur to a marked degree in pathological processes.

Nerve cells show wide morphological variations in different parts of the nervous system. Even within relatively restricted areas the nervous elements may be of many different types. They may be small or large with pyramidal, rounded or irregularly shaped bodies. The number, structure, length and arrangement of their processes also show wide variations. Only those features common to the majority of nerve cell types can be described.

The neuron

The neuron consists of a *body* or *perikaryon* and two types of process—the *dendrite* and the *axon* (axis-cylinder process, fig. 313). The bodies of the nerve cells lie within the gray matter of the central nervous system or in outlying ganglia, e.g., posterior spinal root, cranial or sympathetic ganglia. The white matter of the brain and spinal cord and of the peripheral nerves is composed of bundles of nerve fibers. The core of each nerve fiber is formed by a process of a nerve cell. The gray matter receives a rich blood supply from the vessels

of the pia mater; the blood supply to the white substance is much less profuse.

By means of special staining methods three structures can be distinguished in the cytoplasm of the cell body (a) *neurofibrils*, (b) *Nissl bodies* or *tigroid substance* and (c) *the internal reticular apparatus of Golgi*. The neurofibrils are very fine filaments which stream through the cytoplasm from dendrite to axon (fig. 314); they enter the latter process and extend to its terminations. The Nissl bodies are granular masses stainable with basic dyes. They give a striped or tigroid appearance to the cell (fig. 315A). They are absent from the region of origin of the axon and vary in size and number in accordance with the functional state of the neuron; they undergo disintegration (chromatolysis) in a fatigued or injured cell or in one whose axon has been sectioned (p. 779). The internal reticular apparatus of Golgi is a coarse network seen within the cells when special methods—e.g., impregnation with silver chromate—are employed which leave the Nissl bodies and the neurofibrils invisible (fig. 315B). The surfaces of most perikarya are covered by a fine network—the *superficial reticulum of Golgi*. The nucleus of the nerve cell contains a well defined nucleolus, but as a rule no centrosome.

Though the nerve cell frequently possesses more than one dendrite the axon is single. The dendrites may divide into numerous branches a short distance from their origin from the cell body to form a tree-like structure (in the central nervous system) or they may run for long distances (several feet, as in the peripheral sensory nerves) before they break into their terminal branches. The axon arises from a small elevation on the surface of the cell body—the *axon hillock*. It may give off short collateral branches or may run as an unbranched fiber, not dividing until it has reached its destination. The dendrite is the receptive process of the neuron, the axon the discharging process, i.e., the former transmits the impulse towards, the latter away from the cell body. Nerve fibers which carry impulses to the central nervous system are termed *afferent*; those conveying impulses from the central nervous system to the periphery are called *efferent*. Purely sensory (afferent) nerves are therefore composed, strictly speaking, of dendrites, and purely motor (efferent) nerves of axons. A mixed nerve contains fibers of both types.

Structure of the nerve fiber

The axons and dendrites so long as they remain within the gray matter are simple protoplasmic exten-

sions of the cell body, but upon entering the white matter they become invested by a layer or lipoid material called *myelin*. This covering is known as the *myelin sheath*. In the peripheral nerves, but not in the central nervous system, the myelin sheath is enclosed in turn by a nucleated membrane, the *neurilemma* or *sheath of Schwann* (fig. 313). In peripheral nerve fibers the myelin sheath is interrupted at regular intervals. The neurilemma dips into the gaps so formed to give the appearance of evenly spaced constrictions known as the *nodes of Ranvier*. Toward its termination the nerve fiber loses its myelin covering, being then clothed simply by the neurilemma. The latter is finally lost, the fiber terminating as a naked axis cylinder. The processes arising from sympathetic nerve cells (post-ganglionic fibers) are devoid of a myelin covering. They are invested simply by a sheath of Schwann and are therefore called *amyelinated* or *nonmedullated* fibers.

FIG. 312. Neuroglia cells. Upper, astrocyte; lower, oligodendroglia cell.

Myelination of fiber tracts in the central nervous system

The nerve fibers in the various conducting pathways receive their myelin sheaths at different ages and it is generally believed that the myelination of a given tract and the time at which it commences to function coincide. The sensory tracts become myelinated first, those of the posterior columns of the spinal cord between the fourth and fifth months of fetal life (human). The spinocerebellar tracts are myelinated later and the motor paths, e.g., corticospinal (pyramidal) tracts do not commence to receive their myelin sheaths until the second month of life and are not completely myelinated until about the second year, or about the time when the child has learned to walk. The fibers of association paths, for the most part, myelinate at still later dates.

Neurobiotaxis

Kappers explains the development of conducting pathways in the central nervous system upon the theory

that the body and dendrites of a nerve cell move, as a result of some attractive force, toward the point from where its stimuli come. Its axon lengthens in the opposite direction. Kappers terms this process *neurobiotaxis*. The nature of the attractive force is unknown, though it has been suggested that neurobiotaxis is a galvanotropic effect, the point in the nervous tissue in receipt of stimuli being electrically negative, presumably, to its surroundings. The theory

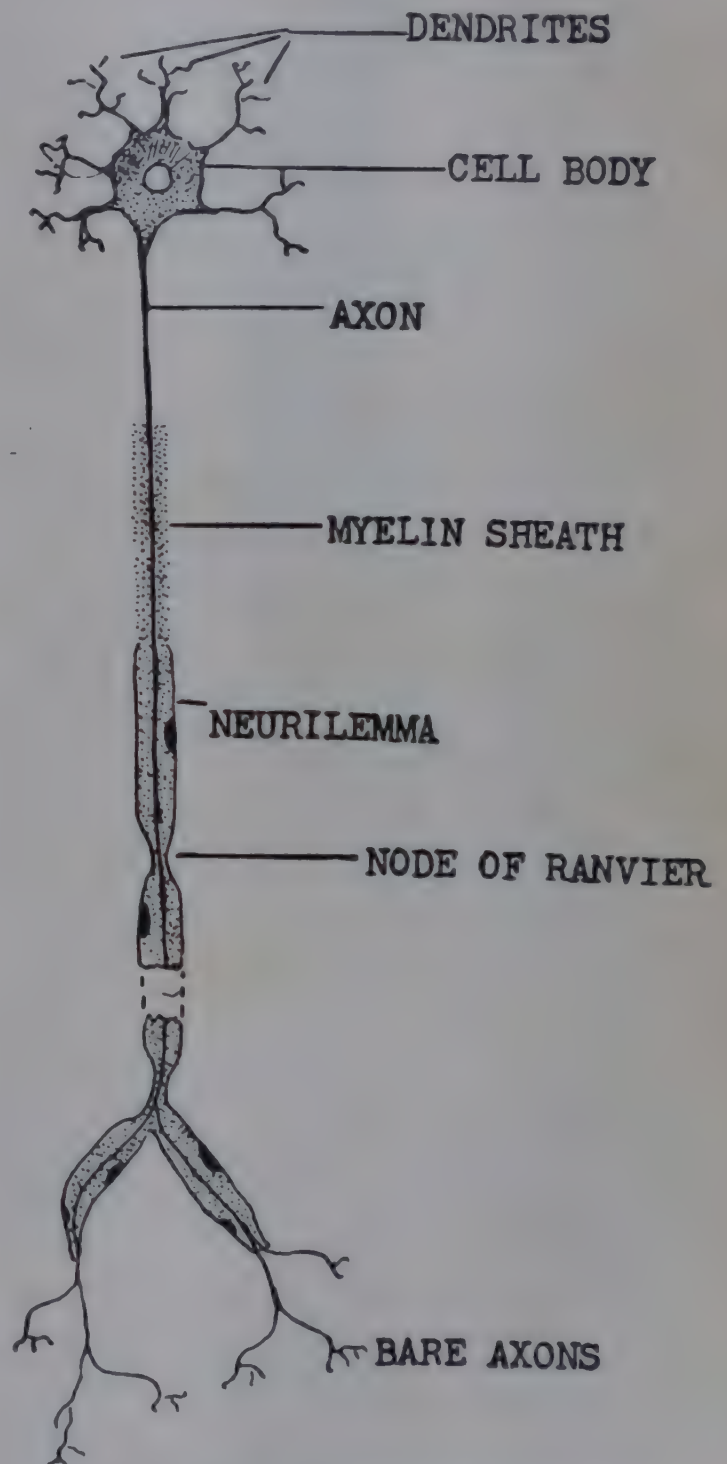

FIG. 313. Showing different parts of the neuron.

of neurobiotaxis offers a ready explanation for the development, as a result of experience and training, of the innumerable reflex arcs within the central nervous system and of the multiplication of association pathways. The close relation of the eye muscle nuclei to the medial longitudinal bundle, through which impulses from numerous sources are received, and the peculiar course of the fibers of the facial nerve within

the pons, are other examples which are believed to illustrate the operation of this principle. The course taken by the facial fibers, which arch over the abducens nucleus, is attributed to the migration of the facial nucleus toward the tractus solitarius and the sensory nucleus of the trigeminal, from both of which the facial neurons receive impulses.

FIG. 314. Showing neurofibrils in a cell from the anterior gray column of the human spinal cord. *ax*, axon, *lu*, interfibrillar spaces; *n*, nucleus; *x*, neurofibrils passing from one dendrite to another; *y*, neurofibrils passing through the body of the cell (from Ranson, after Bethe and Heidenhain).

NERVE DEGENERATION AND REGENERATION

When a nerve fiber is divided the portion peripheral to the point of section, being separated from the body of the cell, undergoes degenerative changes. It is generally believed that the degenerative process does not start first at the point of section and progress to the periphery, but that it involves all parts of the fiber simultaneously, even to the finest terminals. The first change is noted in the neurofibrils which become tortuous and show irregular thickenings. The myelin sheath next becomes swollen and breaks up into small ovoid segments (fig. 316). Later, decom-

FIG. 315. A, showing Nissl bodies; B, internal apparatus of Golgi.

FIG. 316. Degenerating nerve stained with osmic acid. A, shows appearance of distal segment of nerve fiber 2 days after section, note large masses of myelin derived from medullary sheath; B, 5 days after section, smaller myelin particles together with droplets of fatty acids and fragmented neurofibrils; C, retrograde degeneration in cell body, disintegration of Nissl bodies.

position of the myelin occurs; droplets of kephalin and lecithin appear; derivatives of the latter—choline, glycerophosphoric acid and unsaturated fatty acids—can be detected. The fatty acids are responsible for the brown staining of the degenerated nerve when treated with osmic acid. The nuclei of the neurilemma proliferate, and the cytoplasm becomes swollen and vacuolated. The neurofibrils undergo fragmentation; they and the protoplasm surrounding them finally undergo complete disintegration, the debris intermingling with the material of the disorganized myelin sheath. Subsequently the degenerated materials disappear, and all that remains of the nerve fiber is the empty neurilemma tube. The foregoing changes were first described by Waller and are spoken of as *Wallerian degeneration*. Alterations (which were not recognized by Waller also occur in the neuron on the proximal side of the section (*retrograde degeneration*). The nerve fiber as far centrally as the first node of Ranvier shows changes similar in nature to those just described. In the perikaryon itself, swelling of the cytoplasm and nucleus occurs and the Nissl granules undergo disintegration (*chromatolysis*). Atrophy of the cell body may ultimately result.

Regeneration. This occurs in peripheral nerve fibers, but not in those of the central nervous system, the presence of a neurilemma being essential for the process. Section of the sensory root of the trigeminal nerve, for example, for the relief of severe neuralgia of the face, is not followed by regeneration of the fibers within the brain. Nor does regeneration of the optic nerve, whose fibers do not possess neurilemma sheaths, occur.

Regeneration is accomplished by a downgrowth of the neurofibrils from the proximal segment of the cut nerve. These enter the empty neurilemma sheath of the distal segment and in time traverse its entire length. The rate of growth in man has been variously estimated (from 1.0 to 4.5 mm. per day); it is influenced by many conditions. The cells of the neurilemma form a protoplasmic matrix for the sprouting neurofibrils. The neurilemma of the lower segment grows upwards and if the gap is not too long joins the neurilemma of the upper segment which has formed around the developing axis cylinder. The myelin sheath is developed some time later. The young axis cylinders may traverse the tissues for relatively long distances in order to enter the neurilemma of the lower segment. The force responsible for this remarkable phenomenon (neurotropism) is unknown. The attraction may be due to the liberation of

chemical substances by the proliferating neurilemma cells of the lower segment. If the gap separating the two segments is wide and occupied by scar tissue, an effectual block may be offered to the regenerating fibers; these nevertheless continue to grow in a tangled, curled fashion and may produce a localized mass of tissue composed of nerve fibers embedded in connective tissue (*neuroma*). In those cases of nerve injury in which, as a result of pressure or crushing, the axis cylinder is interrupted without division of the neurilemma, the conditions for regeneration are most favorable.

The remarkable rapidity of regeneration of preganglionic sympathetic fibers has been demonstrated by Haimovici and Hodes. In a three-stage operation upon cats large section of the sympathetic chains below their cervical portions were excised. Stimulation of the cephalic end of a cervical sympathetic stump as early as 54 days after the last stage of the operation caused pupillary dilatation and retraction of the nictitating membrane.

The regenerating fibers of one nerve will grow into the sheath of the lower segment of another, though less readily than into its own sheath, and even the fibrils of a sensory nerve will grow into the distal segment of a motor nerve or vice versa. The central stump of one nerve will not, however, grow into the central stump of another. The proximal end of the hypoglossal or spinal accessory, for example, has on many occasions been anastomosed to the distal end of a paralyzed facial nerve with a successful functional result. Cannon, Binger and Fitz united the phrenic in cats to the cervical sympathetic low in the neck and later observed a rise in metabolism, nervous excitability and increased heart action which were attributed to stimulation of the thyroid by impulses discharged from the respiratory center. This experiment was repeated by Horrax, and more recently by Friedgood and Cannon, with essentially the same result. The effect is probably not a direct one upon the thyroid but is due to stimulation of the pituitary and the release of its thyrotropic hormone. Balance and Duel, also experimenting with cats, anastomosed the central end of the hypoglossal to the peripheral cut end of the cervical sympathetic, and reported that the normal pupillary reactions were restored. Restoration of function does not follow the union of a motor with a sensory nerve, nor of a cholinergic with an adrenergic nerve (p. 950).

It has been shown by Tello in animals and by

Duel in man that when a nerve has been severed a much better functional result is obtained if from 2 to 3 weeks are allowed to elapse before the divided nerve is sutured. The reason for this is that the degenerated material in the distal segment has had time to be cleared away; thus, an unobstructed neurilemma tube is left for the downward growth of the neurofibrils of the upper segment. Otherwise, apparently, some of the neurofibrils upon meeting the degenerated debris are diverted from their course.

Degeneration of the facial nerve in the facial canal as a result of middle ear disease (Bell's palsy, p. 860), trauma, etc., has been treated with outstanding success by Duel. The affected portion of the nerve is excised and a graft, constituted of a section of the anterior femoral cutaneous nerve, is used to fill the gap. For the reason just given the latter nerve is sectioned and left in place for 2 or 3 weeks before it is employed in the grafting operation.

Electrical reactions of nerve and muscle. Reaction of degeneration

A motor nerve may be stimulated through the skin by either the faradic (interrupted) or the galvanic (constant) current. The muscle contracts so long as the faradic current flows but only during the make (closure) or break (opening) of the galvanic current; for a given strength of current closure shocks are more effective than opening shocks. In testing the reactions one electrode is placed upon the skin of some indifferent part of the body (*indifferent electrode*) and another smaller electrode (*stimulating electrode*) is placed upon the skin overlying the nerve trunk or muscle which it is desired to stimulate. In the latter instance the nerve terminals within the muscle are stimulated, not the muscle fibers themselves. The stimulating electrode is applied over that part of the muscle which gives a response with the least strength of current; this is spoken of as the *motor point* and corresponds to the point of entrance into the muscle of the motor nerve. When the stimulating electrode is attached to the positive pole of the battery it is called the *anode*. The current enters the muscle by this electrode and leaves the body by the indifferent electrode which is then called the *cathode*. When the galvanic current is reversed, the stimulating electrode becomes the cathode and the indifferent electrode the anode. Normally the least strength of current is required when the cathode overlies the muscle and the circuit is closed. The response which follows such a shock is called the *cathodal closing contraction* (abbreviated C.C.C.). The next most easily elicited response is the *anodal closing contraction* (A.C.C.), i.e., when the stimulating electrode is the anode and the current is closed. The *anodal opening contraction* (A.O.C.) is less easily evoked than the last, and the *cathodal opening contraction* (C.O.C.)

requires the strongest current of all. The four actions in the order of the strength of current required for their elicitation may be expressed thus:

$$C.C.C. < A.C.C. < A.O.C. < C.O.C.$$

The normal relationship between current strength and these responses is also shown in the following table.

STRENGTH OF CURRENT	REACTION
Weak	C.C.C.
Medium	C.C.C. and A.C.C.
Strong	C.C.C., A.C.C., A.O.C.
Very strong	C.C. tetanus, A.C.C., A.O.C. and C.O.C.

The investigation of these reactions is of considerable value in the detection of degeneration of a motor nerve and in the diagnosis of a lower from an upper neuro lesion (p. 865). Lengthening of the chronaxie of nerve occurs during the earlier stages of its degeneration; it therefore fails to respond to the brief shocks of faradic stimulation but a sluggish contraction of the muscle follows stimulation with the galvanic current. Later the nerve becomes quite incapable of being excited by either the faradic or the galvanic current. When the nerve terminals have degenerated the chronaxie of the muscle is lengthened and the faradic current applied directly to the muscle causes no response; the muscle responds, however, though in an abnormal manner, to the galvanic current, the fibers being *directly* stimulated. The response of the muscle shows the following features. (a) Sluggishness of contraction and relaxation. (b) The response is elicited with a weaker current than normally, i.e., the muscle is hyperexcitable to the galvanic current. (c) The anodal closing contraction (A.C.C.) may often be elicited more readily, i.e., with a weaker current, than the cathodal closing contraction (C.C.C.). Thus, $A.C.C. < C.C.C.$

These changes in the electrical responses of nerve and muscle, namely, loss of excitability of nerve to faradic and galvanic stimulation, failure of the muscle to respond to faradic stimulation and the abnormalities of the reaction to galvanic stimulation just described constitute the *complete reaction of degeneration* (C.R.D.). When the nerve is still capable of being excited by galvanic but not by faradic stimulation but the muscle responds weakly or not at all to the faradic current, the reaction of degeneration is said to be incomplete—*partial reaction of degeneration* (P.R.D.).

THE PHYSIOLOGICAL PROPERTIES OF THE NERVE FIBER

EXCITABILITY AND CONDUCTIVITY

The nerve fiber may be stimulated electrically, thermally, chemically or mechanically. Any one

of these types of stimulus causes a change in the nerve at the point of stimulation which may be termed the *local excitatory state*. If this attains a certain value a wave of excitation is transmitted along the nerve fiber. The propagated disturbance is referred to as the *nerve impulse*, and its passage from point to point along the fiber as *conduction*.

THE CHARACTERS OF A STIMULUS

A stimulus may be defined as any change in the environment of a tissue which causes it to react. In experimental work the electric current is usually employed as the stimulus on account of its convenience and the accuracy with which it can be measured. It also leaves the tissue undamaged. In order to induce a local excitatory state in a nerve of sufficient value to set up an impulse, a stimulus must answer the following requirements.

(a) *Intensity or strength*

When electrical stimulation is employed the intensity corresponds, practically, to the voltage. It is well-known that while a strong stimulus will cause a response, a weaker one may fail to do so. The stimulus which possesses just sufficient strength, and no more, to set up an impulse is said to have an intensity of *threshold* (*liminal*) value. Stimuli of less strength than this are called *subthreshold* (*subliminal*) or *subminimal*. A subthreshold stimulus does not, however, leave the nerve unaffected for, if a second stimulus also of subthreshold strength, or a series of such stimuli, be sent into the nerve an impulse is set up. The first stimulus is believed to cause a local excitatory state, or "local potential" (Hill), which, though of too low a value to set up an impulse, can be built up to the requisite level by a second, or a series of subthreshold stimuli, applied at short intervals. The phenomenon is spoken of as the *summation of inadequate stimuli*.

(b) *Duration*

When a constant current is passed through nerve or muscle, excitation occurs only when the circuit is completed. For this reason the duration of the current flow was believed in the past to bear no relationship to its ability to excite. The strength of the current and the rate at which this developed to a maximum ((a) and (b) above) were considered to be the sole factors determining the effectiveness of the stimulus. Though it is true that no physiological effect is produced in the nerve by prolonging the period of current flow indefinitely,

nevertheless the current must flow for a certain period in order to be effective. For example, high frequency alternating currents of very high voltage (tesla) may be passed through the body with impunity.¹ Presumably then, a certain period of time is required for the current to bring about those changes in the nerve upon which the excitatory state depends. The brief effective period following the commencement of the current flow is called the *serviceable* or *utilization time* (*temps utile*). It is measured in thousandths of a second. When, for instance, a current of a certain voltage and having a duration of say 3 sigmas (σ)² just fails to excite the tissue, then either increasing the voltage or prolonging the duration of the current causes a response. Or, if a current of a certain voltage and duration is just capable of exciting the tissue, reducing either of these factors renders the stimulus ineffective. The length of the utilization time varies in different tissues, but for the frog's gastrocnemius it is about 3.0 sigmas. Beyond the utilization period no relationship exists between the intensity and the duration of the current. Therefore when the current is of indefinite duration its effectiveness depends entirely upon its intensity. The intensity (voltage) of a current which when allowed to flow for an indefinitely long period is just capable of exciting the tissue (intensity threshold) is called the *rheobase*. The relationship between strength and duration of current is shown in figure 317.

CHRONAXIE. It is evident from the foregoing paragraphs that the excitability of a tissue may be determined in one or other of two ways: (a) by ascertaining the minimal strength of a current which when allowed to flow for an unlimited period will excite (intensity threshold), or (b) by measuring the minimal time during which a current of a standard strength must flow in order to excite (duration threshold). Lapicque employs the latter or, as he has termed it, the *time characteristic* or *chronaxie*, considering it a more accurate measure of excitability. A current having a strength twice the rheobase is employed, and the minimal duration of flow necessary for excitation is measured. *The chronaxie may therefore be briefly defined as the shortest duration of a current necessary for excitation when its strength is twice the rheobase.*

¹ Heating of the tissues traversed by the current occurs however.

² A sigma or milisecond (m.sec.) = $\frac{1}{1000}$ second.

Determinations of chronaxie may be carried out by the use of (a) a *constant current* which by means of a special type of rheotome is allowed to flow through the tissue for a very brief accurately measured period, (b) *condenser discharges*. The duration of a condenser discharge is proportional to the capacity (C) of the condenser, provided the resistance (R) in the discharge circuit remains constant. By charging condensers of different capacities (measured in farads) to different potentials, currents of any desired duration or voltage can be employed. In order to render any variation in the resistance of different tissues negligible a high resistance (15,000 to 20,000 ohms) is introduced into the discharge circuit. In determining the chronaxie by means of condenser discharges the current of minimal voltage required for excitation is first determined, a very high capacity, i.e., one with a long discharge, being used. The threshold voltage (rheobase) is then doubled and the lowest capacity is found

FIG. 317. Strength-duration curve. The line A B E represents a strength of current twice the rheobase (C D F). The distance A-B therefore represents the chronaxie, i.e., the required duration for excitation of a current having a strength twice the rheobase. The distance C-D indicates the utilization time.

(shortest duration of discharge) which will produce a response at the higher voltage. The result is obtained in microfarads. Since the time, or chronaxie, is proportional to the product of the capacity and the resistance in the discharge circuit, the result can be converted into seconds by the following formula:

$$\text{Chronaxie} = C \text{ (farads)} \times R \text{ (ohms)} \times K.$$

$$(K = 0.37)$$

Rapidly reacting tissues have a shorter chronaxie than the more slowly acting. The chronaxies of smooth muscle and its nerves are longer than those of skeletal muscle and somatic nerves. The tissues of cold-blooded animals have, in general, longer chronaxies than the tissues of higher forms. Flexor muscles have shorter chronaxies than extensors and the chronaxies of the more rapidly acting white muscles are shorter

than those of the red. Nerve fibers of large diameter and of more rapid conduction respond to shorter durations of current than do the thin and slower fibers. The chronaxies of sensory nerves are in general about the same as those of the corresponding motor nerves. The chronaxie of the ventricular muscle, contrary to expectation, is shortened by vagus stimulation, or by drugs such as acetylcholine which slow the cardiac rate and lengthened by accelerator stimulation or by drugs, e.g., atropine and adrenaline, which cause acceleration. The chronaxie of the junctional tissues is about three times longer than that of auricular or ventricular muscle. The chronaxie of the gastric muscle is also shortened by vagus stimulation. The chronaxie is lengthened by cold and shortened by a rise in temperature. Stretching cardiac or smooth muscle reduces the chronaxie; and that of skeletal muscle is lengthened by fatigue and shortened by adrenaline. The utilization time (temps utile) of a tissue varies with its chronaxie, being about 10 times the value of the latter. Thus the chronaxie of the frog's gastrocnemius is 0.3σ , the effective period is 3.0σ .

In table 73 are compared the values for chronaxies and utilization periods for different tissues.

The theory of isochronism. Lapique maintains that normally the chronaxie of a muscle and that of its nerve are of the same order—the value of one not being greater than that of the other by more than 100 per cent. He claims that this so-called *isochronism* is essential for the transmission of the impulse from nerve to muscle. A chronaxie difference greater than 100 per cent between a muscle and its nerve or between any other two successive parts of the conducting pathway (i.e. between neurons), is termed *heterochronism*. It acts as a block to the passage of the impulse. Certain muscular poisons act, it is supposed, by inducing heterochronism. Curare, for example, which does not paralyze either the muscle or its nerve was previously supposed to act upon a special “receptive substance” situated between the nerve ending and the muscle fiber. According to Lapique, the drug acts by lengthening the chronaxie of the muscle but leaving that of the nerve unaffected, i.e., heterochronism is induced. In support of the theory, it is pointed out that when a nerve-muscle preparation is treated with either veratrin or strychnine the muscle can no longer be stimulated through its nerve. Veratrin shortens the chronaxie of the muscle, strychnine that of the nerve. In either case heterochronism is induced. When, on the other hand, the preparation is treated with the two drugs simultaneously the impulse is not blocked since, the chronaxies of both nerve and muscle being shortened, isochronism is maintained. The onset of muscular

fatigue is attributed to the development of heterochronism between the muscle and its motor nerve.

The theory of isochronism has been criticised by Rushton, to whose article the reader is referred; this observer was unable to confirm Lapicque's finding regarding the actions of curare, veratrine and strychnine. At the best the theory appears to be only an approximation and strict isochronism is not a necessary condition for neuromuscular transmission.

Chronaxies in the human subject have been investigated under various physiological conditions and in many pathological states by Bourguignon and others. Condenser discharges are employed, an indifferent electrode being placed upon the skin over the sternum and the stimulating electrode, as the cathode (p. 780), upon the skin overlying the nerve or muscle to be

of a stimulus increases gradually to its maximum value, this must be much greater in order to evoke a response than when the rise in intensity is more rapid. The type of electrical stimulus usually employed rises to its maximum value within $\frac{1}{1000}$ second; however, if the strength of a current, which at this rate of change was just capable of evoking a response, rises more slowly to its peak excitation does not occur.

In seeking an explanation of this fact it might reasonably be assumed that the changes (e.g., ionic redistribution) in the nerve fiber associated with the local excitatory state or "local potential" (V) built up as a result of the stimulus, are opposed by processes of a

TABLE 73

SPECIES	TISSUE	CHRONAXIE	TEMPS UTILE	DURATION OF CONTRACTION
		σ	σ	seconds
Dog	Ventricular muscle	2.0	—	0.16
	Ventricular muscle during vagal stimulation	0.8	—	—
	Bundle of His	6.0	—	—
Frog	Gastrocnemius	0.3	3.0	0.1
	Stomach	100	—	15-20
	Sciatic nerve (conduction 30 m. per second)	0.3	3.0	—
Turtle	Ventricular muscle	9.0	80	—
	Leg muscles	1-2	—	1.0
Crab	Claw muscle	12	300	0.5
Leech	Nervous chain (conduction 0.4 m. per second)	30	—	—
Man	Flexors of thigh	0.10-0.16	—	—
	Extensors of thigh	0.44-0.72	—	—
	Flexors of arm	0.08-0.16	—	—
	Extensors of arm	0.16-0.32	—	—
	Retina	1.2-1.8	—	—
	Vestibular N	14-22	—	—
	Taste buds (tip of tongue)	1.6	—	—

investigated. The chronaxies in the new-born child are about 10 times longer than those of the adult. The longer chronaxies are in agreement with the much slower movements of the infant. Heterochronism exists between the muscles and their nerves until about the 15th month (walking age). The lengthening of the chronaxie of a degenerated nerve and its muscle has already been mentioned (p. 780). In diseases of the central nervous system all muscles which are the seat of paralysis show lengthened chronaxies and in progressive nervous disease those groups of muscles of similar chronaxies are usually attacked more or less simultaneously.

(c) *The rate of change in the intensity of the stimulus —accommodation in nerve*

Rapid change in environmental conditions is an essential factor in excitation. When the intensity

reverse kind tending to restore the nerve to its resting condition. If the stimulus increases in intensity at a sufficiently rapid rate the building up processes outstrip those of a restorative nature until the local potential reaches a critical value, when excitation (impulse production) occurs. When the current ceases to flow V returns gradually, and it is assumed exponentially, to its original value (V_0). According to Hill, the simplest possible expression for the return of V to V_0 is:

$$\frac{dV}{dt} = (V - V_0)K.$$

Where K is the *time-constant of excitation*. The chronaxie then is $K \times 0.693$. In theory it is more precise, in defining K , to deal with the decay of V to V_0 than with the rise of V_0 to V , as the former is then not affected by the nature of the stimulus used.

A second time factor in excitation called the "*time-constant of accommodation* (λ)" has been studied by Hill and Solandt. It is a measure of the rate of change in the critical value of V , which may be designated as the threshold U , under the influence of the stimulus. If the stimulus rapidly reaches the strength required for excitation, U is constant and independent of the previous history of the nerve, but if the stimulus intensity increases more gradually the threshold rises from its resting value (U_0) to some higher value (U). λ is determined by measuring the rate at which U returns to its initial level (U_0). The relationship may be formulated thus;

$$\frac{dV}{dt} = \frac{(U - U_0)}{\lambda}$$

Thus, whereas K is the time-constant of the rate of decay of the excitatory state or local potential, λ is the rate at which, after accommodation, the threshold returns to its original value. The value of λ (35 sigmas for sciatic nerve of the frog and 58 for human ulnar nerve) is normally from 10 to 20 times that of K . However, K and λ vary independently of one another.

The time factor of accommodation is altered by several conditions, the most notable being changes in calcium ion concentration. An increase in concentration of ionic calcium reduces the value of λ , that is, the neuromuscular tissues accommodate more readily, which means that more rapid changes in stimulus strength are required for excitation. Reduction in ionized Ca, as in tetanic states, exerts the reverse effect—increased value of λ , and reduced accommodation of the neuromuscular tissues which are in consequence excited by relatively slow rates of change in the strength of the stimulating current (see p. 702). If the calcium ion concentration is sufficiently low there may be a complete absence of the phenomenon of "accommodation."

THE NERVE IMPULSE

The nerve impulse is a self-propagated disturbance. That is to say, the energy for the transmission of the impulse is derived from the nerve fiber over which it passes. Nervous conduction therefore depends upon the state of the fiber at successive points reached by the impulse. The impulse resembles a spark traveling actively along a train of gunpowder rather than a wave transmitted passively through air or water. In either of the latter two instances in contrast to the first, the energy is derived from a source other than the medium through which the wave travels and the force and amplitude of the wave become gradually reduced with distance. To carry further the analogy drawn between the impulse and the burning train of gunpowder—if a section of the

powder fuse is dampened in advance of the spark the latter becomes less intense as it passes through the dampened section, and travels more slowly. Upon reaching a succeeding dry portion the spark flares up again to its previous intensity and velocity, and so long as the powder remains dry is transmitted without change to the end of the fuse. In a comparable way, if the activity of a segment of nerve is depressed by treatment in a chamber with a narcotic (alcohol or ether vapor) the

FIG. 318. Upper drawing, diagram of nerve (peroneal of cat) in narcotizing chamber to illustrate experiment of Davis, Forbes and associates. S, stimulating electrode. Leadoff electrodes at 1, 2, and 3 within the chamber, and 4 outside. Circuit completed through an indifferent electrode at 5. G, galvanometer for recording action currents. Nerve in chamber exposed to alcohol vapor. The results of this experiment gave no evidence of conduction with a decrement. The action currents from all three leads within the chamber were reduced to practically the same degree. Lower drawing contrasts the different views advanced regarding conduction of the impulse through a narcotized region of nerve. It will be noted that in all three the impulse regains its full value upon entering healthy nerve (from Davis, Forbes, Brunswick and Hopkins).

impulse undergoes a reduction in amplitude and velocity in its passage through the narcotized region, but upon reaching the untreated nerve beyond, regains its original value, and is transmitted unchanged to the termination of the nerve. The question then arises whether the strength of the impulse in its passage through the narcotized section of nerve is suddenly reduced or whether the reduction is progressive. In other words, would the impulse suffer a greater reduction if it were made to traverse a long section of narcotized

erve than if it passed through a short stretch? Until recently it was thought that a gradual or progressive impairment of conduction, i.e., *conduction with a decrement*, occurred. The propagation of the impulse over narcotized nerve was therefore supposed to be different from that along normal nerve. If the narcotized section were long enough, complete extinction of the impulse would result; in this region, therefore, the impulse would resemble a wave transmitted through air or water. From his experiments, in which the long nerve of the Japanese toad was employed, Kato could obtain no evidence that there was a progressive decline in the strength of the impulse. He came to the conclusion that the impulse suffered instantaneous reduction upon entering the region of narcosis and underwent no further reduction during its transmission along the narcotized section. Conduction was therefore *decrementless*. Kato's findings have been confirmed by Davis, Forbes, Brunswick and Hopkins (see fig. 318) but it is pointed out that on theoretical grounds there must exist a short transitional portion of the nerve at the junction of the normal and the narcotized section, 7 mm. or less in length, where progressive decline in the impulse occurs. Beyond this the impulse is conducted throughout the length of the narcotized section without further reduction.

Conduction rates

The velocity of the nerve impulse varies in different nerve fibers in accordance with their diameters, the thicker fibers conducting more rapidly than those of smaller diameter. In the large motor fibers of the mammal the rate is from 50 to 100 meters per second. Sensory nerves of the skin being of smaller diameter have slower conduction rates. Non-medullated fibers conduct more slowly than medullated. Some of the fibers subserving pain sensation and those of the sympathetic nervous system have a very slow conduction rate (see also p. 802).

The following table from Hill (*Chemical Wave Transmission in Nerve*, Cambridge University Press), gives the conduction rates in the nerves of several different animals.

Medullated nerve, mammal, 37°C., about 100 m./sec.
Medullated nerve, dogfish, 20°C., about 35 m./sec.
Medullated nerve, frog, 20°C., about 30 m./sec.
Non-medullated nerve, crab, 22°C., 5 and 1.5 m./sec.
Non-medullated nerve, mammal, 37°C., about 1 m./sec.

Non-medullated nerve, olfactory of pike, 20°C., 0.2 m./sec.

Non-medullated nerve, in fishing filament of *Physalia*, 26°C., average 0.12 m./sec.

Non-medullated nerve, in Anadon, 0.05 m./sec.

Compare the velocity of sound in air at 0°C., 331 m./sec.

By an indirect method of measurement Carmichael and his associates found the rates of conduction in various human postganglionic sympathetic nerves to be from 0.85 to 2.30 meters per second. The lower figures were obtained for the nerves of the leg, the higher ones for the nerves of the chest.

The "all or none" principle

A stimulus which is just capable of exciting a nerve fiber (threshold stimulus) sets up an impulse which is no different from one set up by a much stronger stimulus. The impulse set up by the weak stimulus is conducted just as rapidly and is just as strong, when judged by the action current developed or the mechanical response of the muscle, as one set up by the strong stimulus. Briefly, the propagated disturbance set up in a single nerve fiber cannot be graded by grading the intensity or duration of the stimulus—the nerve fiber gives a maximal response or none at all. To make use again of the train of gunpowder analogy—the flame of a match applied to the powder fuse will start a traveling spark no less intense than one started by the flame of a torch. The restoration of the strength of the impulse to its original value after passing from a narcotized region into healthy nerve (p. 784) also shows the "all or none" nature of nervous conduction. The well known fact that a strong stimulus applied to a nerve trunk causes an action current of greater amplitude, and a greater muscular response than a weaker stimulus appears to contradict the all or none principle. The nerve trunk, however, is composed of many fibers each of which supplies a group of muscle fibers. The weak stimulus excites only a proportion of the units of the nerve, a maximal stimulus excites them all. For example, the *cutaneous dorsi muscle* of the frog is supplied by a nerve which contains only 8 or 9 fibers; each of these innervates about 20 muscle fibers. Keith Lucas found that when the nerve was stimulated by shocks, gradually increasing in intensity, the muscular responses did not show a similar continuous rise in amplitude; on the contrary, the responses of the muscle increased in a series of well-defined steps; that is, increasing the stimulus intensity produced no effect for a time upon the amplitude of the muscular response, but then a

slight increase in strength of stimulus produced a sudden rise in amplitude. The steps were never greater in number than the number of fibers, and were due, it was concluded, to additional fibers becoming excited as the strength of stimulus reached a certain value.

It must also be remembered that the all or none principle applies only for the condition of the nerve at the point where, and the moment when, the impulse arises. A stimulus which will give rise to a response of a certain magnitude under one condition of the nerve may give a much smaller response under other conditions, e.g., during the relative refractory period, (p. 787), narcosis, oxygen lack, etc.

Variations in the frequency of the impulses in a single nerve fiber

The magnitude of the muscular response is determined not only by the number of neuromuscular units excited but also by the frequency of the impulses transmitted along the individual nerve fibers. When a motor nerve is stimulated maximally by a single induction shock, an impulse passes along each nerve fiber and the "volley" of impulses upon reaching the muscle causes a single contraction of all its fibers—a so-called muscle twitch. If the nerve is stimulated again after a certain brief interval a second volley of impulses is discharged and a second contraction occurs, which becomes superimposed upon the first to produce a greater muscular response. This is spoken of as *summation of contractions*. A series of volleys reaching the muscle at sufficiently short intervals will prevent any relaxation of the muscle between separate volleys. That is, the individual contractions become fused to produce a sustained maximal response or *tetanus*. Adrian and Bronk isolated a single fiber of the phrenic nerve in the cat and recorded the action currents passing along the fiber during normal respiration and after clamping the trachea. The action currents increased in frequency from between 20 and 30 per second during quiet breathing to between 50 and 80 during the forcible respiratory movements induced by the asphyxia. But no change in the amplitude or form of the electrical waves occurred. At the lower rate of discharge the individual contractions were incompletely fused (*incomplete tetanus*). At the higher rates the tetanus was complete and the tension developed by the contraction maximal. It might be thought that when the impulses are of low frequency and there is, in consequence,

incomplete fusion of successive twitches the contractions of a muscle would be uneven and jerky. This would be so did the impulses discharged from the nerve centers travel synchronously along the different fibers composing the motor nerve. At low frequency, however, the impulses are discharged asynchronously, i.e., not as a volley but rather as a scattered fire rifle shots. Groups of muscle fibers are therefore activated asynchronously, the contractions of different groups overlap and a smooth steady contraction of the muscle as a mass results. At high frequencies the impulses are discharged along the separate nerve fibers synchronously, i.e., in series of volleys, but owing to the fusion of the successive contractions the action of the muscle as a whole is also smooth and sustained. Results comparable to those described for the phrenic were obtained from a single fiber of a motor nerve supplying a skeletal muscle (N. to the peroneus longus, to the tibialis anticus or to the quadriceps). A reflex discharge of impulses was produced by stimulation of the foot and the impulses recorded from the motor nerve, all the fibers of which except one had been severed. The impulse frequency varied from 20 to 90 per second with the strength of the stimulus. *The amplitude of the recorded electrical changes was not increased by the strongest stimulation, i.e., the action potential is "all or none in nature."*

By inserting a pair of very closely approximated electrodes into a muscle, it was found possible to record the action currents of a small group of muscle cells supplied by a single nerve fiber (Adrian and Bronk). A fine copper wire (gauge 36), enamelled except for its tip, was passed down a small hypodermic needle. The exposed wire projecting from the point of the needle forms one electrode and is connected to the input of an amplifier. The needle itself constitutes the other electrode and is connected to earth. The action currents may be led, after amplification, to a capillary electrometer or oscillograph and recorded photographically or converted into sound by a loud speaker, their rhythm then being picked up by ear. When the concentric needle electrodes were inserted into the human triceps and a voluntary movement made, the records indicated that the impulses arriving along a single nerve fiber varied with the strength of the contraction from 5 to 50 per second. No electrical changes were observed when the muscle was completely relaxed. At the higher rate the record showed minor waves. These were interpreted as indicating that additional neuro-muscular units also came into action during the stronger contraction. At the lower frequency the active fiber groups are fewer and conse-

quently more widely separated; the electrical responses from neighboring groups therefore do not complicate the electrical record of the group immediately surrounding the electrodes. When certain muscles were excited reflexly, e.g., peroneus longus, tibialis anticus of the rat, there was little evidence that the stronger contraction was due to more fiber groups coming into play, i.e., to impulse discharges over a greater number of motor nerve fibers; the grading of the contraction appeared to be due chiefly to variations in the frequency of the impulses.

The absolute and relative refractory periods of nerve

Within a certain brief interval following the passage of an impulse along the nerve fiber a second stimulus, however strong, is unable to evoke a

FIG. 319. Curve of the recovery of excitability in the sciatic nerve of the frog. Two stimuli were applied to the nerve, the second stimulus being separated from the first by various time intervals and of just sufficient strength to excite. Intensity of stimulus is plotted along the ordinate, time along the abscissa. The interrupted horizontal line indicates the threshold strength of current required to excite the resting nerve. During the absolute refractory period (about 0.003 sec. in this instance) a stimulus, however strong, will not excite. The excitability returns gradually during the next 0.02 sec. (relative refractory period) (after Adrian)

response. This interval is called the absolute refractory period. In a frog's sciatic nerve at a temperature of about 15°C. the absolute refractory period has a duration of between 2 and 3 sigmas (0.002 to 0.003 second). Its duration is the same or slightly longer than that of the action potential "spike," (see pp. 789-791). It is much shorter in mammalian nerve (about 0.4 sigmas). Succeeding this period of absolute refractoriness is one in which the nerve, though it will not respond to as weak a stimulus as it did before the passage of the impulse, will respond to a somewhat stronger one. The excitability of the nerve gradually increases and the strength of stimulus necessary for excitation becomes progressively less (fig. 319). In the end, the restoration of excitability is

complete and the nerve responds to a stimulus of no greater strength than that which is capable of exciting a resting nerve. This period following the absolute refractory phase and during which the excitability gradually rises to normal is called the *relative refractory period*. It lasts for from 0.01 to 0.02 second or at any rate the excitability of the nerve has returned to about 95 per cent of the resting value by this time. (Full recovery however may not be attained until the lapse of 0.1 second.) It should be pointed out that the failure of the nerve to conduct a second impulse is not due simply to lowered excitability at the *point in the nerve where the original stimulus was applied*, for during the absolute refractory period a stimulus applied to any other point upon the nerve likewise fails to set up an impulse. The passage of the impulse along the nerve leaves in its wake a change of state like a trail of ash after the ignition of a powder fuse. For the moment the impulse consumes the entire resources of the nerve fiber (Adrian). The burned fuse must have its store of energy replenished by laying a fresh train of powder grains before a second spark can traverse the path of the first. So also, a certain time is required for the changes associated with the passage of the impulse to become reversed and the nerve restored to its resting condition (polarized state, see also p. 791).

The refractory period renders a continuous excitatory state of the nerve impossible just as the corresponding period in cardiac muscle assures rhythmical contractions and prevents summation and tetanus. The propagated disturbances resulting from repeated stimulation of the nerve fiber may be compared to a stream of bullets rather than to a stream of water. Fusion or summation of impulses does not occur. The refractory period obviously must also limit the frequency of the impulses. In the mammal the absolute refractory period is about $\frac{1}{1000}$ second. The intervals between impulses, obviously, cannot be shorter than the absolute refractory period; the maximum impulse frequency is therefore around 1000 per second. At this rate the impulses are travelling into the *relative* refractory period of their predecessors and are consequently weaker. In frog nerve with its refractory period of from 2 to 3 sigmas, the maximal impulse frequency is between 250 and 300 per second.

THE SUPERNORMAL AND SUBNORMAL PHASES. The relative refractory period is succeeded by one lasting for from 3 to 15 sigmas, in which the nerve fiber is

hyperexcitable. This is followed in turn by a state of subnormal excitability which persists for from 15 to 70 sigmas.

THE ELECTRICAL CHANGES IN NERVE

The current of injury

When a pair of electrodes are placed a short distance apart upon the surface of an uninjured and resting nerve (or muscle) and connected through a galvanometer, no current flows and no deflection of the instrument occurs, since the entire surface of the nerve (or muscle) is positively charged. When, however, one part of the tissue is injured the membrane at this point becomes depolarized (see membrane theory, p. 791) and, in consequence, negative to the positively charged uninjured surface. When the two electrodes are now placed one on the injured and the other on the uninjured part and connected through a galvanometer a constant current flows through the instrument from the uninjured (+) to the injured (-) section and in the opposite direction through the length of the tissue. This is known as the *current of injury* (or *demarcation current*) (fig. 320, I).

The current of action

Active tissue is also relatively negative to resting tissue. The former corresponds to the zinc or negative pole of a battery, the latter to the copper or positive pole. If, therefore, two electrodes are placed upon a section of nerve and connected through a galvanometer, as shown in fig. 320 II, A, stimulation of the nerve at S causes a movement of the galvanometer indicator first in one direction and then in the other. The movement may be photographed, when a diphasic curve—a wave above the base line followed by one in the opposite direction—is obtained. This is the result of the propagation of the wave of excitation along the nerve from one electrode to the other. When the wave reaches the tissue beneath the first electrode this region becomes negative to the resting tissue beneath the second electrode. A current flows through the galvanometer from the resting to the active region. A wave above the base line is inscribed in the record (fig. 320 II, B). During the lapse of time from the passage of the wave from beneath the first electrode to its arrival at the second no current flows, and the galvanometer indicator returns to the zero position (fig. 320 II, C). The arrival of the excitation wave beneath the second electrode

now renders the tissue here negative to the tissue under the first electrode, and a current through the galvanometer, but in a direction opposite to that of the current previously seen. As the nerve beneath the second electrode returns to the inactive state the galvanometer comes to rest. A wave below the base line is thus recorded (fig. 320 II, D and E). The diphasic electrical change is called the *current of action*. If a current of injury is set up by crushing the nerve between the second electrode stimulation of the nerve beyond the first electrode sets up an action current.

FIG. 320. I, current of injury; II, current of action. Description in text. The small arrows indicate flow of the current in the galvanometer leads; the arrow, in II A, indicates the direction of spread of wave of contraction.

which, being in the opposite direction to current of injury, causes this to be reduced. This reduction in the strength of the current of injury causes a movement of the galvanometer indicator toward the zero position; this is spoken of as *negative variation*. The excitation wave does not reach the tissue beneath the second electrode so it is blocked by the injured tissue so a second oppositely directed wave does not appear, i.e., variation is *monophasic*.

So far as is known the propagated disturbance in nerve is invariably accompanied by an electrical change. In fact there is no evidence to indicate

the nerve impulse and the traveling electrical wave are not one and the same. At any rate they are very intimately related and the investigation of the electrical changes in the nerve fibers by the method of recording is therefore the most convenient and at the same time the most sensitive and accurate means we possess for studying the frequency, speed and strength of the nerve impulse. For example, the number of successive electrical impulses traversing the nerve is taken as representative of the frequency of the impulses; the speed and amplitude of the impulse is judged from the speed and amplitude of the electrical response. The action waves are of the same general form in all types of nerve fiber; this is taken as an indication that the impulses in the different nerve fibers are fundamentally similar.

After-potentials. Following the main action potential, called the "spike" potential as it is now usually called, a number of smaller electrical changes appear in tracings obtained by the more sensitive methods of recording. These are known as *after-potentials*. They appear as a series of spikes, but in their simplest form, as a single response. They consist of an initial negative potential (i.e. of the same direction as the action potential) followed by a positive deflection of much smaller amplitude (about 0.2 per cent of the height of the action potential) but of longer duration. The negative after-potential has a duration in rapidly conducting fibers of about 15 μ , the positive after-potential of one second or more. The after-potentials show much greater variability with experimental conditions than does the action potential. A tetanizing current increases both negative and positive after-potentials; with such a current a second negative potential frequently appears which may last several minutes. The spike coincides approximately with the absolute refractory period, the negative after-potential with the supernormal and the positive after-potential with the subnormal phases of excitability, respectively.

The "spike" and the after potentials can also be recorded from the spinal cord during stimulation of a nerve root. The spike potential arises from the stimulation into the cord of the fibers of the dorsal root. Gasser concludes for several reasons that the after-potentials are derived from internuncial neurons.

Compound nature of the action current recorded from a nerve trunk

Langley, Bishop and Gasser studied the action potential of mixed nerve trunks by means of the cathode ray oscillograph.

Like any instrument previously employed for this purpose, e.g., the string galvanometer or the capillary electrometer, the moving part of this instrument—a stream of electrons—possesses practically no mass and

is in consequence inertialess. It is therefore capable of recording almost infinitely rapid changes in electrical potential. The instrument consists of an evacuated tube through which the electron stream is thrown against a fluorescent screen upon which it produces a spot of light. On either side of the electron stream is placed a vertical plate. A potential difference is created between the pair of plates; the electric field thereby set up across the path of the stream deflects it horizontally. By means of a rotating commutator the deflections are repeated 10–20 times per second. The spot of light is thereby converted into a horizontal streak. A second pair of horizontal plates is placed one above, the other below, the electron stream. These are connected with the nerve whose action current is timed to reach them at the instant that the stream is deflected horizontally by the vertical plates. An upward deflection of the electron stream results with the production of a standing wave. This is photographed. The speed of the horizontal movement of the spot of light enables the time factor to be calculated, and can be varied by changing the distance between the pair of plates; the horizontal movement corresponds to the movement of a kymograph, though of course its rate is very many times faster. The upward deflection is analogous to the rise of a muscle lever. The magnitude of the action potential is determined from the height of the wave. Before reaching the recording system the action current is amplified several thousand times by passing it through a three-stage amplifier.

In a mixed nerve the wave of action potential ("spike"), which by slower methods of recording appears simple, has been shown in reality to be compounded of three waves differing from one another in amplitude and conduction rates. They have been designated, respectively, *alpha*, *beta* and *gamma* waves (fig. 321). For example, when the potential changes are recorded as 12 mm. from the point of stimulation the wave is simple; at 31 mm. its descending limb shows a hump. At 46 mm. two waves may be distinguished from the main wave which is now considerably reduced in amplitude. At 82 mm. three separate waves are clearly seen. The three waves may be compared to runners in a race who, though starting together, gradually become scattered as the faster contestants outstrip the slower. In the dog's sciatic nerve the alpha wave has a speed of about 90 meters per second, and the beta and gamma waves 50 and 30 meters per second respectively. The three types of wave have the same general form but the alpha wave has a greater amplitude than the others; the gamma wave is the smallest. Through histological counts of the fibers of different sizes in the mixed nerve the respective action waves have been identified with fibers of

different diameters. In the peroneal nerve of the frog, for instance, there are three groups of myelinated fibers whose diameters are around 16, 10 and 5 microns, respectively. The fibers of largest size (16 microns) are responsible for the *alpha* wave, the intermediate and the smallest fibers give rise respectively to the *beta* and *gamma* elevations. That is, the larger the fiber the faster its conduction rate. The excitability and length of the refractory period of the fiber also varies with the diameter, the smaller ones possessing a higher threshold and a longer refractory period than the larger.

A correlation has also been established between fiber size and the action potential wave, on the

FIG. 321. Cathode ray oscillograph records of the action currents in the sciatic nerve of the bullfrog after conduction from the point of stimulation through the distances (in millimeters) shown at the left (see text) (modified from Erlanger, Bishop and Gasser).

one hand, and the function and course or distribution of the fibers on the other. When the peripheral end of the sciatic was stimulated and the action current recorded from one of the anterior roots of the nerve, only the *alpha* wave appeared. All three waves, however, can be recorded from the sensory root. It is therefore concluded that the large efferent and afferent fibers of the mixed nerve give rise to the *alpha* wave. The *beta* and *gamma* waves are due to action potentials arising solely in afferent fibers.

When a *motor* branch of the femoral nerve of the dog is stimulated and the action potential led from the trunk of the nerve, only *alpha* waves are obtainable as in the case of the anterior root.

Stimulation of a branch of the nerve going to the skin (saphenous) gives *beta* and *gamma* waves but not the *alpha* elevations. It is evident from the preceding nerve-root experiments that the *alpha* waves are produced in the large efferent (motor) and afferent fibers (muscle-sense) of the muscular branch and that the *beta* and *gamma* waves are developed in afferent fibers subserving skin sensations.

The fibers responsible for the three waves α , β , and γ , just described are now referred to as the *A* group, since later work of Erlanger and Gasser has revealed the existence of two other groups of peripheral nerve fibers of slower conduction rate, lower excitability, and which give rise to action potentials of much smaller amplitude. When a stimulus considerably stronger than one required to excite the *A* group is applied to the mixed nerve and the amplification of the instrument increased, the elevations due to the excitation of these fibers appear. The fibers are referred to as the *B* and *C* groups respectively. When the action potential was recorded from the nerve at a distance of 9 mm. from the point of stimulation, the first of these waves, designated *B*, appeared about 15 σ after the crest of the *gamma* wave of the *A* elevation. The second wave, designated *C*, appeared about 110 σ after the termination of *B*. The *B* elevation is also sometimes, like the *A* elevation, compound and the *C* elevation usually so. The fibers giving rise to the *B* elevation have conduction rates midway between those given by the slowest fibers of the *A* group and those given by the *C* group. In the dog the rates of the *B* group vary between 10 and 20 meters per second; those of the *C* group between 0.3 and 1.6 meters per second. The *B* fibers are excited by a weaker stimulus than that necessary to excite the *C* group and both groups as already mentioned have a higher threshold than the *A* group.

To sum up:

The *A* group of fibers consists of: (a) Large efferent (motor) and afferent (muscle sense) fibers of the mixed nerve which are responsible for the *alpha* wave. (b) Afferent cutaneous fibers (touch and temperature) which are responsible for the *beta* and *gamma* waves.

The *B* group, i.e., those responsible for the *B* elevation, enter the mixed nerve through the gray rami communicantes. They are evidently post-ganglionic sympathetic fibers.

Fibers belonging to the *C* group are found in: (a) Anterior roots and white rami. These are

fferent and myelinated (pre-ganglionic sympathetic fibers). (b) Gray rami. (c) Posterior roots. These are afferent and non-myelinated. They possibly transmit sensations of pain.

B and C types of fibers are found in both autonomic and muscular nerves.

It is impossible to identify the C and B groups of fibers by means of fiber diameter or structure since

It has been suggested that the non-myelinated C fibers of the posterior root subserve protopathic sensibility (p. 803), while epicritic impulses are conveyed by certain fibers of the A group.

THE MEMBRANE THEORY OF NERVOUS CONDUCTION

Conduction, according to this theory, is a surface phenomenon. The nerve fiber is surrounded by a semi-permeable membrane or surface

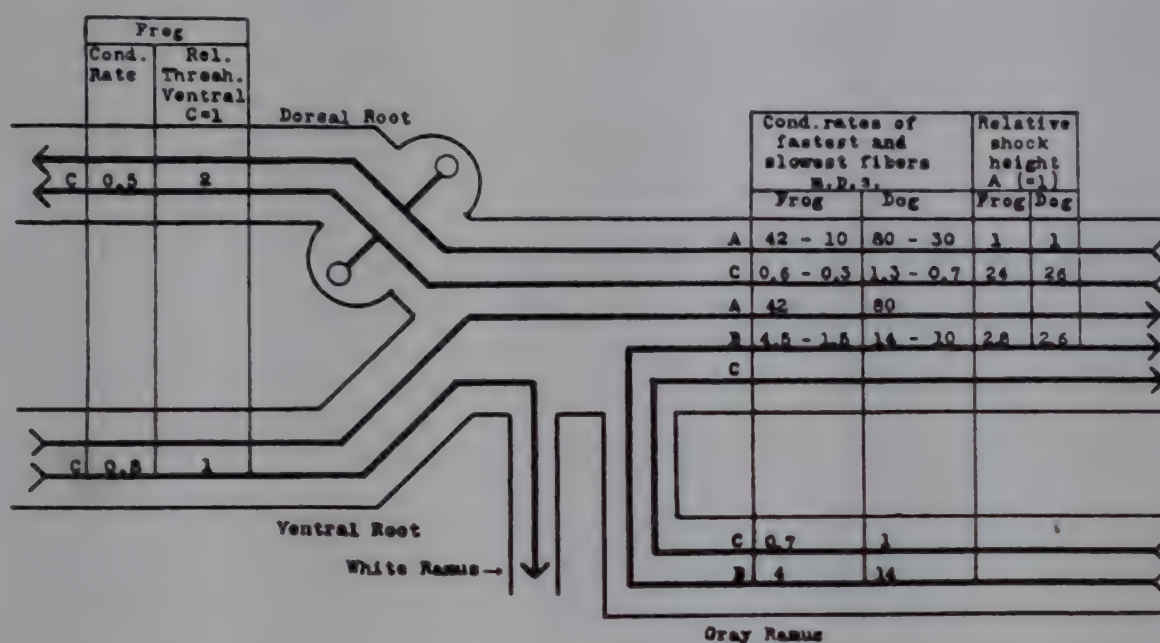

FIG. 322. Diagram indicating the sources and a typical set of reactivities of the fiber groups that contribute to the action potentials of mixed nerve and spinal roots (after Erlanger and Gasser).

FIG. 323. Illustrating nervous conduction according to the membrane theory (see text).

There is not the correlation between fiber size and conduction rates that is seen in the case of fibers making up the A group. For instance, the very slowly conducting C fibers of the anterior roots and white rami are relatively large, having diameters of 4μ or more. Furthermore, though all the A fibers are myelinated the C group, as pointed out above, may be either myelinated or non-myelinated. The distribution of the different fiber groups are summarized in the following scheme (fig. 322) from Erlanger and Gasser.

film which is polarized when the nerve is at rest. That is, the surface film separates a layer of cations on its outer side from a layer of anions on its inner side. A stimulus applied to the nerve increases the permeability of the membrane at the point of stimulation with the result that a redistribution of ions and depolarization of the membrane occurs. This point of the nerve becomes thereby relatively negative to the inactive (polarized) section of nerve immediately adjacent. A potential difference is set up and a current flows between the active and inactive sections. This secondary current in turn causes depolarization and activation of the adjoining region which, being now relatively negative to the next section results in a current being again set up between these two which depolarizes the latter. Thus the currents set up between contiguous, inactive and active regions serve as successive stimuli and the wave of depolarization spreads down the nerve; the disturbance set up by the original artificial stimulus is in this way propagated automatically (see fig. 323). The depolarized state persists for a short time after the passage of the impulse; during this time the nerve is refractory. The return of

excitability is dependent upon the restoration of the polarized state.

Perhaps the greatest support for the membrane theory is afforded by the experiments of Lillie who has prepared a metal model which behaves in a manner comparable to that of nerve. A film of oxide forms upon an iron wire placed in strong nitric acid. When such an oxide-coated wire is then immersed in a weak solution of acid, which would cause gradual solution of an untreated wire, no reaction results. The metal is in a so-called passive state, being comparable to a resting nerve. When, however, the wire is "stimulated," e.g., touched at one point with active iron or some other base metal, scratched with a piece of glass in order to break the protective oxide film, or an electric current applied to it, a reaction (electro-chemical reduction) is set up which, accompanied by effervescence and the formation of a dark-colored lower oxide, sweeps down the wire. If two parts of the wire be connected with a galvanometer a current flows through the instrument during the spread of the reaction. If the acid bathing the wire is of a certain concentration, the protective film reforms in the wake of the reaction. If a second "stimulus" is applied after the film has reformed, but not before, a repetition of the phenomenon occurs. The resemblance of the reaction of the iron wire to the nerve impulse is very striking. Both are electrical in nature; the film of oxide is analogous to the surface film postulated for the nerve fiber. So long as the protective oxide is intact a potential difference exists between the wire on the inside and the surrounding acid. Discontinuity at any point in the film causes this region to become negative to other regions and a wave of depolarization is propagated to the end of the wire.

In its behavior the wire model shows the following remarkable resemblances to that of nerve.

(1) The rate of propagation of the reaction is of the same order as that of the nerve impulse.

(2) The "stimulus" must be of a certain intensity (threshold). A stimulus greater than the threshold causes no greater effect ("all or none" principle).

(3) The wire, as already pointed out, is irresponsive for a short time after the reaction has passed (absolute refractory period); while the film is reforming the reaction is set up with greater difficulty (relative refractory period).

(4) When an electric current is employed to activate the wire it must rise to its maximal intensity rapidly in order to elicit the reaction.

(5) The activating current must flow for a certain minimal length of time (chronaxie) in order to produce the effect.

In the wire model a demonstrable temporary break in the continuity of the oxide deposit is produced. It is presumed that the excitation of nerve is associated with a corresponding change (increase in permeability) in the surface film surrounding the nerve fiber. Though

such a permeability change has been demonstrated in certain slowly conducting protoplasmic systems, evidence for its occurrence in nerve is indirect. In the case of nerve and other protoplasmic systems alteration in permeability is associated with chemical changes—the processes underlying the excitation of nerve and the transmission of the impulse are therefore as in the case of the iron wire model, essentially electrochemical in nature.

METABOLISM OF NERVE AND BRAIN

It has been thought until comparatively recent years that a negligible expenditure of energy accompanied the transmission of the nerve impulse.

FIG. 324. Diagrammatic representation (not to scale) of the heat production due to each nervous impulse, indicating how the observed heat resulting from a tanic stimulation is built up of these units. The horizontal lines represent the delayed heat, starting at a maximum rate of 0.05 "C" units and slowly falling to zero in about 10 mins. The vertical lines represent the initial heat which probably is largely produced during the first 4σ at a rate 5000 times greater than that at the start of the delayed phase (after Gerard).

the latter was believed to be dependent upon physical rather than upon chemical processes. Though it had been recognized that conduction eventually failed in the absence of oxygen, the fact did not prove that conduction itself was due to oxidative processes. In order to show this would be necessary to demonstrate an increase in the oxygen consumption and in the carbon dioxide production during activity. An increase in carbon dioxide production of active nerve over that of resting nerve was observed by Tashiro in 1913. This was confirmed by Parker, and increased oxygen consumption during excitation was shown by Fenn. Earlier attempts to demonstrate heat production in active nerve were unsuccessful, but in 1926 Hill, using a thermopile composed of over two hundred thermocouples,

ected a rise of $\frac{7}{10,000}^{\circ}\text{C.}$ in the temperature of nerve as a result of stimulation lasting 10 seconds.

HEAT PRODUCTION IN NERVE

The resting sciatic nerve of the frog in oxygen liberates about 70×10^{-6} calories³ per gram of nerve per second. In nitrogen the resting heat production falls gradually to about 25 per cent of this value. During stimulation in oxygen, at the rate of 280 shocks per second, an increase in heat production occurs of 40×10^{-6} calories per gram of nerve per second. At this rate of stimulation the heat resulting from a single impulse is about $40 \times 10^{-7} \frac{14}{100,000,000}$ calories per gram of nerve fiber. The heat production of nerve during activity is only about $\frac{1}{400,000}$ of that produced in an equivalent weight of muscle stimulated to the same degree.

As in the case of muscle the heat is given off in two phases—the *initial heat* and the *delayed* or *recovery* heat. The initial heat is, however, less than 10 per cent of the total heat,⁴ the ratio of initial to delayed heat being 1:9 as compared with 1:1.24 in the case of muscle heats. The rate of generation of the initial heat is some 5000 times greater than that of the delayed heat. The former lasts for only a few thousandths of a second, being an intense explosive outburst as compared with the slowly developed but greater delayed heat (p. 324). The delayed heat is accompanied by the consumption of oxygen and is evolved in two stages. The first of these lasts for a few seconds, and the quantity of heat is of small magnitude; the second lasts for 10 to 30 minutes and contributes the greater portion of the delayed heat.⁵ Increase in the length of the stimulus does not increase the heat production, whereas increase in the frequency of stimulation causes an increase in heat production up to 100 per cent. The heat per second, however, does not increase proportionately with the increase in frequency of stimulation, so the heat per impulse is actually reduced. When the shocks are at the rate of 280 per second the heat production per second is maximal and the heat per impulse (since each impulse is travelling

in the relative refractory period of its predecessor) is only a quarter of that generated by a single isolated impulse. The heat production of the central nervous system is enormously greater than that of nerve fibers amounting to from 600 to over 2000×10^{-6} per gram per second for the spinal cord of the frog.

CARBON DIOXIDE PRODUCTION AND OXYGEN CONSUMPTION

The resting sciatic of the frog produces in the neighborhood of 0.6 cu. mm. CO_2 per gram of nerve per minute. The corresponding O_2 consumption is about 0.7 cu. mm. The resting respiratory quotient is therefore around 0.8. During activity an extra 0.25 cu. mm. of O_2 per gram of nerve per minute is consumed and a somewhat smaller quantity of extra CO_2 produced. The extra metabolism of the nerve resulting from activity has an R.Q. of about 0.90 (Meyerhof and Schmidt).

The extra oxygen consumed by the nerve resulting from activity occurs during the period of delayed heat. It continues for a considerable time—15 minutes or more after the impulse has passed. The quantity of oxygen consumed agrees well with the heat produced at this time, upon the basis that the latter is the result of the oxidation of ordinary food materials. Like the heat production the oxygen consumption per impulse falls with a rise in frequency of stimulation, though of course the total consumption per minute increases. Increasing the strength of the stimulus beyond that necessary to excite all the fibers does not increase the oxygen consumption.

CHEMICAL CHANGES

(a) IN THE ABSENCE OF OXYGEN. Placed in nitrogen a *resting* nerve undergoes a reduction in its glycogen and free sugar contents and an accumulation of lactic acid. The lactic acid production proceeds slowly and in about 3 hours has reached a maximum rate of 7 mg. per 100 grams of nerve per hour; it then falls gradually to zero. The total acid production is about 100 mg. per 100 grams of nerve (0.1 per cent). This is not attained until the end of 24 hours, at which time the carbohydrate store of the nerve becomes exhausted. Immersion of the nerve in a solution of glucose (but not of galactose or fructose) causes lactic acid production to continue at the maximum rate (7 mg. per cent) for days—or until conversion of the added glucose has occurred. When the nerve is *stimulated* in nitrogen there does not result, however, as in the case of muscle deprived of

³Small calories.

⁴Hill found that the initial heat of crustacean nerve is only 2.25 per cent of the total heat, which, however, is much greater (215×10^{-3} per second per gram of nerve) than that of frog nerve. Beresina and Feng obtained similar values for crab nerve.

⁵The cause of the initial heat is unknown. It may be of chemical in nature and due to the breakdown of phosphocreatinine or may be derived, as Hill suggests, from an electrical source, namely, the discharge of an electric double layer—a condenser—located at the surface of the fiber. See A. V. Hill, "Chemical wave transmission in nerve." Cambridge, University Press, 1927.

oxygen, an increased accumulation of lactic acid. Also when oxygen is re-admitted lactic acid does not disappear or does so very slowly. Oxygen consumption of the nerve is somewhat greater than usual after a period in nitrogen—an indication that nerve runs into debt for oxygen during a period of anoxia. In the absence of oxygen, nerve, unlike muscle, continues to respond to stimulation for a considerable time. It shows a progressive fall in excitability but does not fail to conduct until the lapse of about 3 hours. The action current or the current of injury gradually decreased during this time but rises again when oxygen is re-admitted. A fall in phosphocreatine content and a rise in inorganic phosphorus also occur.

In the asphyxiated nerve the delayed heat production declines no more rapidly (if anything less so) than the initial heat, whereas in the case of a muscle contracting in the absence of oxygen most of the recovery heat is abolished (p. 618). In nerve, therefore, *both conduction and the recovery process can apparently be accomplished for a time after the external oxygen supply has been cut off.*

(b) IN THE PRESENCE OF OXYGEN. In the case of the excised *resting nerve* free sugar gradually disappears but the glycogen content remains unchanged and *no lactic acid is formed*. These observations indicate that the function of the resting nerve is probably maintained in part by energy derived from the combustion of sugar. Energy is also probably derived from the breakdown of phospholipins. *During activity* phosphocreatine is broken down but the glycogen content of the nerve remains unaltered. Sugar does not disappear more rapidly than during rest, nor is lactic acid produced. The glycogen-lactic acid cycle which is so prominent in the metabolism of muscle therefore appears to play no part in nerve fiber conduction. The immediate source of the energy for conduction is believed to be derived from the breakdown of phosphocreatine which is resynthesized after the passage of the impulse. The ultimate source of the energy for the recovery process in nerve is unknown.

It has been thought that the nerve fiber was incapable of oxidizing lactic acid or of synthesizing lactic acid to glycogen, but, as mentioned above, when an accumulation of lactic acid occurs as a result of asphyxia small amounts do disappear upon the re-admission of oxygen. Also, in a nerve soaked in sodium iodoacetate the phosphocreatine disappears and the nerve soon fails to respond, but if lactate be supplied the survival time is considerably lengthened and

oxygen consumption increased (Feng). (The addition of lactate causes no increased oxygen consumption in normal nerve.) These and other observations indicate that the inability of the nerve to oxidize lactic acid is not absolute but that, under certain circumstances at any rate, such does occur.

Small quantities of *ammonia* (about 0.3 mgr per cent per hour) are produced by resting nerve and about double this amount during activity. The source of the ammonia is probably adenylypyrophosphate. The *inorganic phosphate* also increases during activity as a result of the breakdown of phosphocreatine and adenylypyrophosphate and, possibly, of phospholipins.

Potassium of nerve. The nerve fiber is exceptionally rich in potassium; Cowan found that the potassium concentration in the nerve of the crab is some 13 times greater than that in crab's blood. But when the nerve is stimulated or deprived of oxygen, potassium diffuses rapidly into the surrounding fluid, but is restored again during rest or in the case of the asphyxiated nerve, after the readmission of oxygen. A nerve at rest and adequately supplied with oxygen does not lose potassium and a potential difference between the surface of the fiber and its interior is maintained. Increasing the concentration of potassium in the fluid bathing the nerve will tend to reduce the potential difference; this procedure also reduces the excitability of the nerve and with high concentrations excitability is completely lost but is restored again when the nerve is placed in sea water. The amplitude of the action current or of the current of injury is also markedly reduced by raising the potassium concentration on the outer side of the nerve. Furthermore, when the nerve is exposed to cold, "blocking" of the impulse occurs at a higher temperature than usual if the nerve has been soaked in a solution containing a high percentage of potassium. Finally, a high concentration of this cation in the fluid in which slices of brain tissue are immersed, greatly increases the production of lactic acid from glucose in the presence of oxygen; in an atmosphere of nitrogen, on the other hand, lactic acid production is depressed by potassium.

These several observations have no doubt shown the importance of potassium in nervous activity but they give little precise information concerning the rôle which it plays. The outward diffusion of K ions is apparently an essential factor in the development of the potential change associated with the conduction of the nerve impulse.

The metabolism of the resting nerve may be considered in terms of the membrane theory (p. 791) to be directed toward securing a certain degree of impermeability of the surface film for the maintenance of the polarized state. The chemical changes associated with activity result in increased permeability and depolarization. During recovery the membrane is repolarized, the energy being furnished by oxidative processes—the battery is recharged. The source of the energy which enables a nerve to continue to conduct for such a long time in an atmosphere of nitrogen is a matter for speculation. The energy for the recovery of the fiber between impulses may be derived from the reduction of hydrogen acceptors in the nerve substance, which thus serve as oxidizing reserves when oxygen is excluded. It has been shown, for example, that a hydrogen acceptor such as *metadinitrobenzene* is able to restore conduction in an asphyxiated nerve (Cohen and Gerard). This substance will also restore motility to asphyxiated spermatozoa. Sodium peroxide and hydrogen peroxide are also capable of restoring the power of conduction in asphyxiated nerve. When, as a result of prolonged stimulation in nitrogen, the oxidizing reserves become exhausted recovery of the nerve cannot be accomplished since energy for the repolarization of the membrane is not available, and conduction fails.

The *brain* (gray matter) when supplied with oxygen oxidizes glucose and, unlike the nerve fiber under the same conditions, produces lactic acid, though in small amounts. Lactic acid is also produced slowly when glucose is added to brain slices *in vitro*. Large quantities of lactic acid are formed, however, by the brain under anaerobic conditions. Glucose is present in brain tissue in about the same concentration as in blood, and is the main substrate for the respiration of the gray matter. The respiratory quotient of the brain is around unity. The gray matter contains only small amounts of glycogen. When the latter is added to brain slices it is broken down very slowly to lactic acid. Hexosephosphate, according to Ashford and Holmes, is not an intermediary in the oxidation of glucose by brain tissue, but the production of pyruvic acid appears to be an essential step. The utilization of glucose by brain tissue is made evident by its addition to brain slices, an increased consumption of oxygen then occurs. The oxygen consumption of brain tissue *in vitro* is also increased by the addition of mannose, fructose, pyruvate or lactate. The large production of lactate under anaerobic conditions and the minimal amounts produced when the oxygen supply is adequate raises the question whether the formation of lactic acid plays any role in the

normal function of the brain. It appears, at any rate, that it does not play an indispensable part in the oxidation of glucose, for nicotine, iodoacetate or hydroxymalonate inhibits the oxidation of lactate but permits glucose to be oxidized. Though lactate is utilized by the brain, glucose appears to be the main source of energy. A respiratory quotient of unity supports the conclusion that the main fuel of the brain is carbohydrate, but more direct evidence for the oxidation of glucose can be cited. Himwich and Fazekas, for example, determined the glucose and oxygen contents of the arterial blood and of blood drawn from the superior longitudinal sinus of anesthetized dogs. They obtained a figure of 13 mg. per 100 cc. of blood for the glucose utilization. The quantity of oxygen which by calculation would be required to oxidize this quantity of glucose is 9.7 cc. The oxygen consumption actually observed was 9.3 cc. Chute and Smythe found that the isolated surviving cat's brain perfused with defibrinated blood used from around 100 to 400 mg. per gram of brain tissue per hour and from 40 to 120 mg. of lactate per gram per hour. There appeared to be a direct relationship between the level of the blood sugar and the quantity of glucose used. In the same preparation the oxygen consumption (calculated from the arterio-venous oxygen difference and the cerebral blood flow) amounted to from 200 to 300 cc. per 100 grams of brain tissue per hour (see also p. 291). These figures are, of course, for the brain as a whole; the gray matter shows a much higher oxygen consumption than does the white matter which is composed mainly of nerve fibers. It has been estimated that the human brain accounts for from 8 to 10 per cent of the basal metabolism, yet mental work increases the basal metabolism to a negligible extent (p. 536). Though the nerve fiber can contract a small oxygen debt the gray matter cannot, and is, in consequence, highly susceptible to deprivation of oxygen. This is especially true of the higher centers. The delirium of pneumonia is due largely to anoxia rather than to toxemia, and the mental aberrations associated with high altitudes are well known. The metabolism of the cerebellar cortex, according to some investigators, is higher than that of the cerebral cortex. Himwich and Fazekas have made the interesting observation that in week-old puppies the medulla and midbrain have a higher oxygen consumption than has the cerebral cortex but the reverse relationship holds true in adult

dogs. The increased oxygen consumption of the higher centers of grown animals is due presumably to their having acquired greater functional importance and assumed a position of dominance over the lower centers.

The brain is also very sensitive to a reduction in its supply of glucose, and when the blood sugar level falls to a certain point, mental confusion, muscular incoordination, convulsions and loss of consciousness result. The hypoglycemic symptoms are quickly relieved by the administration of glucose, mannose or fructose, but not by pyruvate or lactate. In the human subject insulin hypoglycemia greatly reduces the oxygen consumption of the brain, but this is quickly restored to normal by the injection of glucose (Himwich and associates). The reduction of the metabolism of the brain and its restoration to normal are closely associated in time with the hypoglycemic symptoms and their relief. Lactate and pyruvate have little effect in raising the oxygen consumption above the low level caused by hypoglycemia. It is quite evident from these facts and other observations already mentioned that glucose plays a very special and vitally important part in the metabolism and functions of the brain.

As might be expected from the relationship between the blood glucose level and the oxygen consumption, the effects of anoxia and of hypoglycemia are in certain respects closely similar, and are supplementary to one another. Hypoglycemic convulsions are induced more readily in

the presence of anoxia, and the effects of the latter are more severe if the blood sugar is depressed.

There is no evidence that the lipids—*cholesterol*, *lecithin*, *cephalin* and *sphingomyelin*—which enter so largely into the composition of brain substance serve any special metabolic need; their function is probably to insulate neighboring nerve fibers from one another.

Quastel and associates as a result of their experiments advance the theory that anesthetics and narcotics bring about unconsciousness by inhibiting the dehydrogenase systems of the brain. They found that the addition of glucose or lactate to chopped brain tissue in the presence of an anesthetic alone was followed by an increased oxygen uptake. After exposure of the brain tissue to anesthetics or narcotics (barbiturates, chloroform, hyoscine) the oxygen uptake was much reduced. However, no doubt has been expressed that anesthetics and narcotics in the dosage ordinarily employed exert their effects in this manner. The majority of the drugs investigated cause the mobilization of the carbohydrate stores through the discharge of adrenaline with consequent reduction in brain carbohydrate and a rise in blood sugar. The reduced respiratory rate demonstrable in brain tissue excised from anesthetized animals and compared with that of controls is attributed to their relatively low carbohydrate content rather than to depression of the action of respiratory enzymes (Emerson).

CHAPTER LXIV

THE REFLEX ARC. RECEPTOR ORGANS. CUTANEOUS AND KINESTHETIC SENSATIONS

The involuntary muscular contraction which results from the stimulation of a sense organ is known as a reflex. The quick withdrawal of the hand from some agent which has inflicted pain or the contraction of the pupil when a light is thrown into the eye are familiar examples of reflex action. The activities of various glands are also largely reflex in nature as are many of the reactions of the vascular, respiratory and digestive systems. The exciting cause of the reflex may make an impression upon consciousness, as when a group of skeletal muscles contracts as a result of a painful stimulus; or, as in the case of reflexes involving the secretion of glands or the activities of smooth muscle, e.g., of the blood vessels, heart or digestive tract, the initiating stimulus as well as the reflex act itself may be entirely unperceived.

THE REFLEX ARC

The anatomical basis of reflex action is the reflex arc which in its simplest form consists of:

(a) *An afferent limb* composed of the *receptor organ*, which upon excitation, gives rise to the impulse, and the *neuron* whose processes (central and peripheral) transmit the impulse to the central nervous system. In the case of the spinal reflex arc the cell bodies of the afferent neurons are situated in the posterior root ganglia.

(b) *An efferent limb* constituted of a motor or secretory neuron which conducts impulses from the central nervous system to an *effector organ*—muscle or gland. In the case of motor spinal reflex arcs, the axons of the efferent neurons leave the cord by the anterior nerve roots and travel in the peripheral nerves; their cell bodies are situated in the anterior horns.

(c) *A center* situated in the gray matter of the central nervous system and consisting of the cell body of the efferent neuron and its junction (synapse) with the central process of the afferent neuron.

As a rule the afferent and efferent limbs do not connect directly in the center, one or more nerve cells being interposed between the two. These are spoken of as *connector*, *internuncial*, or *intercalated neurons* (fig. 325). The stretch reflex (p. 322) as shown by Lloyd is carried out through

a reflex arc of only two neurons, but the majority of the spinal reflex arcs in higher animals consist of several neurons, and in most reflexes each afferent neuron makes connection through collateral branches and internuncial neurons with a large number of motoneurons (fig. 326).

Injury, leading to loss of function of any one part of the reflex arc, is sufficient to destroy the function of the whole.

THE RECEPTOR ORGANS

The afferent fibers end peripherally either as bare unmyelinated filaments or in accessory structures called *receptors* (fig. 327). These are highly specialized to respond most effectively to one or other type of stimulus. When stimulated appropriately an impulse or a series of impulses is sent along the afferent fiber. Receptors are situated in the skin, muscles, tendons, etc., and in such special organs as those of sight, hearing, smell and taste. They are also contained in the walls of the respiratory and digestive tracts, mesentery, carotid sinus and other internal structures. Through receptors in these various situations information is continually being transmitted over somatic and autonomic pathways to the central nervous system. Those receptors which respond to stimuli arising in the outer world, e.g., those of the skin, eye, ear, etc., are called *exteroceptors*. Of these, those which make perception at a distance possible, i.e., those situated in the visual, auditory or olfactory sense organs, are sometimes referred to as *distance receptors* (telereceptors). Receptors lying in the mucous linings of the respiratory or digestive tracts and which, though not in immediate contact with the outer world, respond to stimuli ultimately derived therefrom are spoken of as *interoceptors*. *Proprioceptors* are those which respond to stimuli originating within the body itself, e.g., in the skeletal muscles, (p. 805) tendons, joints, heart, carotid sinus, gastro-intestinal wall, etc. Though each variety of receptor responds most readily to one particular type of stimulus—*adequate stimulus*—many will respond in some degree to stimuli of other types. The retina, for instance, can be stimulated mechanically or electrically and the receptors of taste,

though responding most effectively to chemical stimuli, may also be stimulated by an electric

them adequately is sometimes used to designate different varieties of reception organ. Thus *tango-* (touch), *chemo-* (taste, smell and the receptors of the carotid and aortic bodies) and *photo-* (sight) *receptors* are spoken of.

shock applied to the tongue. A terminology based upon the type of stimulus which excites

CUTANEOUS SENSATIONS

The sensations which may be aroused by stimulation of the skin are *touch*, *cold*, *warmth* and *pain*. Each of these sensations, except the last,

FIG. 328. Showing cold spots (A) and hot spots (B) within an area on the palm of the hand. The sensation in each case was most intense in the black areas, less intense in the lined and mildest in the dotted areas. In the blank portions no definite sensation was aroused (after Goldscheider).

mediated by a receptor or sense organ possessing distinctive structural features.

The presence of discrete endings subserving the several cutaneous sensations enables small areas to be mapped out upon the skin which are specific for one or other sensation. The areas are called touch, cold, heat or pain "spots" respectively in accordance with the sensation which their stimulation arouses (fig. 328).

If the *afferent nerve* fiber supplying one or other

receptor organ is excited *directly* by the application of the type of stimulus, e.g., touch, heat, etc., for which the receptor is adapted to respond, the characteristic sensation is not, as a rule, aroused; a painful sensation usually results.¹ Moreover, reflexes can usually be elicited much more readily by stimulating the receptors than by applying the stimulus directly to the afferent nerve, and certain reflexes cannot be evoked at all by direct excitation of the nerve fiber. Pressure upon the pad of the hind foot of the "spinal dog," for example, causes a strong extension of the whole limb—the *extensor thrust*—whereas no form of stimulus applied directly to the afferent nerve itself will produce this reflex (Sherrington). The afferent fiber before terminating in the receptor organ or as a free nerve filament loses its myelin sheath and neurilemma and appears as a naked axon (p. 777).

LIGHT TOUCH. Tactile sensation—the sensation aroused by light contact—is subserved by three types of receptor, *Meissner's corpuscles*, *Merkel's disks* and a basket-like arrangement of nerve fibers, surrounding the base of a hair follicle (Fig. 329). Meissner's corpuscles are situated in the papillae of the skin, just beneath the epidermis. They are unevenly distributed, being sparsely scattered over such a region as the volar aspect of the forearm but numerous in the skin of the hand, foot, nipple and lips, and in the mucous membrane of the tip of the tongue. They are well organized structures, consisting of irregularly coiled nerve endings with capsules of connective tissue. *Merkel's disks* consist of groups of three or more cup-shaped disks with a reticulated appearance. The nerve fiber upon approaching a group of such structures breaks up into branches, one going to each disk. Merkel's disks are found in the skin of the snouts of pigs and other mammals and in the finger-tips, lips, mouth and glans penis of man. The basket-like arrangement, surrounding the base of a hair follicle consists of a number of short, vertical, nerve filaments which end in small bulbous expansions. They are stimulated by any slight movements of the hairs.

Inequality of pressure with consequent deforma-

tion of the skin surface is the essential factor in the stimulation of touch receptors.

The sensation of light touch is tested by bringing a wisp of absorbent cotton in contact with the skin, or by the use of von Frey's esthesiometers. These consist of a series of hairs of graded thickness attached at right angles to wooden holders. The pressure in grams required to bend each hair is known. In order, therefore, to express the sensitivity of the skin to touch in terms of pressure the hair is found by trial which, when pressed vertically upon the skin until bending occurs,

FIG. 329. Cutaneous receptors. A, Meissner's corpuscle (touch); B, Krause's end bulb (cold); C, Ruffini's end organs (warmth); D, Pacinian corpuscle (deep pressure); E, bare nerve endings in cornea (pain) (in part from Bainbridge and Menzie, *Essentials of Physiology*, Longmanns, Green and Co.).

causes the sensation. The sensitivity of the skin to touch varies widely in different regions. The minimal pressures required are given in table 74. When hairy parts, such as the back of the hand, are lightly brushed with a tuft of cotton wool the hairs serving as levers deform the skin, and thus cause stimulation of touch receptors situated in the neighborhood of the hair follicles. Shaving the hairs over such parts greatly reduces the sensitivity to touch. Other regions quite devoid of hairs such as the finger tips and lips, on the other hand, possess the highest degree of tactile sensibility.

¹ Heinbecker, Bishop and O'Leary have reported that tactile as well as painful sensations may be aroused by the electrical stimulation of the nerve trunk. The experiments were carried out upon the exposed nerves of human subjects. Stimuli of low intensity applied to the nerve aroused the sensation of touch, those of greater intensity a sensation of pain. No other type of sensation was experienced by the subjects.

TACTILE LOCALIZATION. When a tactile stimulus is applied to a point upon the skin the normal subject is capable of recognizing the location of the stimulus with a high degree of accuracy. Localization is much more precise over some regions, such as lips and tips of the fingers, than over others, such as the forearm or thigh. In certain nervous diseases this localization is grossly impaired. In lesions of the cerebral cortex the subject usually, according to Horsley, when asked to locate the stimulus indicates a point some distance upon its *proximal* side. In some diseases, notably hysteria, the subject feels the stimulus at a corresponding point on the opposite side of the body; this phenomenon is called *allocheiria*.

TABLE 74

The minimal pressures required for the elicitation of the sensation of touch from various cutaneous regions
(After Meyers)

REGION	GRAMS PER SQUARE MILLIMETER
Nose.....	2
Lips.....	2.5
Tip of finger.....	3
Back of finger.....	5
Upper arm, inner surface of thigh.....	7
Back of hand.....	12
Calf, shoulder.....	16
Abdomen.....	26
Front of leg, sole of foot.....	28
Back of forearm.....	33
Loin.....	48

The localization of a cold, hot or painful sensation is very inaccurate unless the stimulating agent actually touches the skin. Thus, heat radiated from a small object about 1 millimeter from the cutaneous surface gives rise to a diffuse sensation. The more accurate localization when contact is made with the skin is evident though the subject experiences no sensation of touch. It is likely, nevertheless, that the tactile receptors are excited, that the failure to appreciate the sensation is due to masking by the stronger stimulus, and that impulses arising in the touch endings are responsible in some manner for the more accurate localization of the other types of stimulus when these are applied directly to the skin.

TACTILE DISCRIMINATION (COMPASS TEST). If two stimuli are applied simultaneously, two distinct sensations are felt, provided the distance between the two stimulated points is sufficiently

great. Thus, when the points of a pair of compasses are blunted or covered with cotton wool and applied to the finger tip, the subject recognizes the duality of the stimulus if the points are more than about 2.3 mm. apart. When they are separated by a shorter distance a single sensation is experienced. The minimal distance at which the recognition of two stimuli is possible varies in different regions, as shown in table 75.

In the case of the limbs the power of discrimination diminishes progressively from the distal to the more proximal segments, and hairless regions in general have a higher discriminating ability than those covered with hair.

A correspondence is also exhibited between the mobility of a part and its discriminating ability. For example, the minimal distance necessary for

TABLE 75

Different cutaneous areas compared with regard to the minimal distance which must separate two stimulated points in order to arouse a double sensation
(After Meyers)

REGION	MINIMAL DISTANCE
	mm.
Volar surface of finger tip.....	2.3
Dorsal surface of third phalanx.....	6.8
Palm of hand.....	11.3
Sole of foot.....	16.0
Back of hand.....	31.6
Back of neck.....	54.0
Middle of back, upper arm and thigh.....	67.1

two stimuli to give rise to a double sensation is less for the fingers and hand than for the arm, shoulder and back, and diminishes progressively over the skin of the face from the region of the ear to the lips.

It should be pointed out that the values given in the foregoing table do not represent the distances separating individual touch receptors. For example, when single stimuli are applied *successively* to different points of the skin of the finger tip the spots from which tactile sensation can be evoked are found to be about 0.1 mm. apart. That is, when compass points are applied to the finger tip and are recognized as two stimuli several (15 to 20) touch spots are included within the intervening space.

TICKLING AND ITCHING. There has been much discussion concerning the origins of these sensations. The tickling sensation appears to be due

to the summed effects of stimulating both touch and pain endings. Section of the spinothalamic tract (which conveys pain impulses) results in the loss of the appreciation of pain but retention of the sense of touch; a tickling sensation cannot be aroused over the analgesic skin. On the other hand, the sense of touch is lost while that of pain is retained, when the skin is rendered moderately ischemic; again, the tickling sensation cannot be elicited. The *itchiness* which is experienced in the region adjacent to a slight injury, or during the healing of a more severe injury when the skin is rubbed, has the same nervous origin, being dependent upon impulses travelling by both tactile and pain fibers, but the *spontaneous* itching which is felt under the same circumstances, appears to be due to the mild stimulation of pain endings alone; more intense stimulation of the same character causes pain. This type of itchiness is affected relatively little by ischemia. Both types of itching are alike in that they are due to a chemical substance acting upon nerve endings and liberated by the damaged cells of the skin. This substance appears to be the same as that which causes the triple response. An extract of skin showing this response when injected into normal skin induces both types of itching. Histamine introduced into the skin has a similar effect. Rothman believes that itching is identical in quality with protopathic pain and is mediated by the C group of nerve fibers.

COLD is mediated by the end organs of Krause (fig. 329 B) and *warmth* probably by the end organs of Ruffini (fig. 329 C).³ Mechanical or electrical stimulation, as well as the application

³ Waterston questions the existence of definite heat and cold spots since he finds that the points from which these sensations can be aroused change from time to time in number as well as in pattern. He states that when the skin is hyperemic the entire surface responds to warmth (punctate distribution being abolished) and he believes that the entire skin surface is potentially sensitive to this sensation, the apparent punctate distribution being due simply to fluctuations in the activity of different areas. The variability in sensation, he suggests, may possibly be related to a corresponding fluctuation in the capillary circulation. The observations of Bazett and associates indicate that the diffuse nature of the temperature sensations on hyperemic skin can be best explained upon the basis of a more ready conduction of heat through the blood stream to neighboring end organs; thus, when the cutaneous blood flow is profuse heat applied to a non-sensitive point in the skin would be conducted rapidly to adjacent warm spots. The observations of Bazett and his colleagues upon the sensitivity of the prepuce support the conception of heat and cold spots and the existence of discrete receptor organs for these sensations as well as for touch (Arch. Neur. Psych. 1932, 27, 189). Waterston's view has not received general acceptance.

of heat itself, will stimulate the latter end organs and give rise to the sensation of warmth. Cold and touch spots are much less numerous than touch and pain spots.

PRESSURE upon the skin considerably greater in degree than that which elicits the sensation of touch stimulates the more deeply lying receptors known as the *Pacinian corpuscles* (fig. 329 D). The sensation of pressure is not, however, a true cutaneous sensation; the Pacinian corpuscles lie in the subcutaneous tissues or inner layers of the dermis as well as in tendons, periosteum and other deep-seated structures; their nerve fibers run chiefly, not in the cutaneous nerves, but in the sensory nerves supplying tendons and blood vessels (see p. 805).

PAIN is subserved by naked nerve endings, there being no organized end organ for this sensation. The pain nerves of the skin are described by Woolard as consisting of non-medullated fibers which terminate in the superficial layers of the dermis in delicate loops lying parallel to the skin surface, or as long naked neurofibrillae. Only occasionally do fibrils penetrate the epidermis. Bare nerve endings mediating pain are also present in the cornea (fig. 329 E) and in serous surfaces (peritoneum, pleura, etc.); touch, cold and warm endings are absent and the corresponding sensations cannot be aroused from these locations. Although it is a general belief that the cornea contains only pain endings and that any stimulus, if intense enough to evoke a response at all, causes pain, it is claimed by some that the sensation of touch without pain can be aroused by a very mild stimulus such as a jet of isotonic saline.

The pain endings do not respond selectively to one variety of stimulus but to any type whether mechanical, chemical or thermal, provided it is sufficiently intense. The pain stimulus, whatever it may be, has one property in common, namely, that it causes or threatens injury. The sensation of pain therefore serves a protective purpose, giving warning of the injurious nature of a stimulus rather than information as to any more specific quality. Stimuli which arouse painful sensations also provoke reflex actions which have the following features. (a) They comprise movements for *protection* or *defense* or for the withdrawal of the part from the noxious agent. (b) They are *prepotent*, other less urgent reflexes being for the time inhibited. (c) They are *imperative*. Such reflexes are called *nociceptive*.

Whereas, the touch spots are more numerous toward the peripheral parts of the body, the pain

spots are more profuse near the roots of the limbs. Thus, in the axillae, supraclavicular fossae and inguinal regions, their number is around 200 per sq. cm., but there are no more than from 40 to 70 per sq. cm. over the palms and soles, the tip of the nose and the ear.

It used to be thought that the production of pain was not a function of any one type of nerve ending, but that any skin receptor if stimulated with sufficient intensity would give rise to the sensation. This conception has been refuted by modern work which indicates that the various types of cutaneous receptors are specific in function (see p. 808).

The nature of cutaneous pain. Pain in the skin, although usually described as of several different kinds, e.g., burning, pricking, cutting etc., is always, according to Lewis, of the same quality, the apparent differences being due solely to variations in the duration of the sensation. A blind-fold subject, for example, is unable to distinguish between the pain caused by a pin prick, a hot point, a punctate electrical stimulus or the plucking of a hair, provided no associated non-painful sensation gives the patient a clue as to the nature of the stimulating agent. These pains would all be described as sharp, "bright" or pricking. A burning pain is experienced when the sensation is more prolonged, whether caused by heat or ultra-violet light or by a chemical or mechanical irritant.

It is a common experience that a single painful stimulus applied to the skin, if intense enough, may give rise to two sensations separated by a short interval. The first pain is short and sharp, the second, more prolonged and severe. The observations of Lewis and Pochin upon this phenomenon indicate that pain impulses are conveyed from the skin by two sets of nerve fibers, one of which is rapidly conducting, the other with a much slower conduction rate. They found that ischemia of the skin of the arm, induced by arresting the circulation, abolished the first response to the needle prick, the second response being unaltered for a time but later became reduced. Cocaine, on the other hand, abolished the second response before the first. It was shown moreover, that the time interval between the two responses was prolonged as the length of the nerve between the point of stimulation and the central nervous system was increased, a fact which seems to demonstrate decisively the existence of a fast and a slow pathway for the transmission of cutaneous pain. The time interval between the two responses is 1.9

sec. when the stimulus is applied to the toe, 1.3 sec. to the knee and only 0.9 sec. to the upper limit of the thigh.

The first painful sensation of the dual response appears to travel by the fibers of rapid conduction belonging to Erlanger's and Gasser's B group (p. 790), for they are more susceptible to asphyxia, whereas, the second pain response is transmitted by the slowly conducting C group of fibers, since they are more readily affected by cocaine.

A third type of pain response follows some little time after certain forms of injury, e.g., scorching, scalding, sun-burn or the application of an irritating agent, and persists for a variable period. Even a slight burn may cause a dull pain which continues for many minutes. This pain evidently is caused by the release of a chemical substance from the damaged tissues and not by direct action of the stimulating agent upon the nerve terminals. Arresting the blood supply to the part intensifies and prolongs the pain. The nature of the chemical excitant is unknown, but it is not H substance (p. 269), potassium, nor acetylcholine; nor is it due to altered pH.

Deep pain. Pain can be provoked by the appropriate stimulation of muscle, bone and periosteum, joints, tendon and fascia, and arteries, and of the thoracic or abdominal viscera. Visceral and referred pain are dealt with in Chapter XLV.

Muscles, tendons and fasciae are especially susceptible to painful stimulation by chemical agents. The injection of a few drops of a 6 per cent saline solution into one of these structures causes pain. Muscle is relatively insensitive to pricking or cutting but pain is aroused by pressure, e.g., pinching or squeezing, or by exercising under ischemic conditions (p. 257). Tension acts also as a pain stimulus for muscle, tendon or fascia. Deep pain is diffuse, usually continuous and poorly localized. Pain occurring in ischemic muscle during activity is due to a chemical irritant produced by the active tissues and which accumulates and stimulates the pain endings when the circulation to the part is arrested or considerably reduced. This substance is referred to as factor P by Lewis and his associates. The soreness of healthy muscles which comes on some hours after exercise is of the same nature.

Periosteum and cancellous bone are very sensitive to the various types of mechanical stimulation, but compact bone is insensitive to drilling or sawing. The arteries give rise to painful sensations when pricked, but the walls of the veins are insensitive

Deep pain differs in certain particulars from superficial pain in that it is not associated with protective reflexes and when severe, is accompanied by sweating, nausea, slowing of the pulse and a fall in blood pressure. The pain is best described as "sickening". Cutaneous pain cannot be appropriately described in this way and it is accompanied by quickening rather than slowing of the pulse, and a rise in blood pressure.

Hyperalgesia and the nocifensor nerves. In many persons an area of tenderness develops around even a small cutaneous injury and spreads over a considerable distance in all directions. The soreness starts within a few seconds, increases to a maximum in from 15 to 30 minutes and lasts for hours or, with a more severe injury, for days. The threshold for pain as tested by a needle prick is lowered only slightly over the area, but the pain when aroused is diffuse, and unusually intense and prolonged. This phenomenon has been studied by Lewis and his associates. Injury was produced by prolonged faradic stimulation of the skin, by crushing a small cutaneous fold with forceps or by direct stimulation of a cutaneous nerve trunk or one of its branches. A similar area of cutaneous hyperalgesia may result from an injury or an inflammatory process involving deep-lying tissue or mucous membrane. Thus, stimulation of a dental nerve or of the mucous membrane of the maxillary antrum is followed by tenderness of the overlying skin of the cheek. Lewis' experiments point to a specific system of nerves in the skin as being responsible for the hyperalgesia. They are believed to be quite distinct from the pain fibers which are stimulated directly by the injurious agent and through which pain sensations are ordinarily registered. This system, which is referred to as the *nocifensor nerves* is pictured as finely branching and rich end-plexus within the skin; it leads into more deeply lying axons which, in turn, run into subcutaneous nerve trunks. The action of this system of nerves serves to ward off further injury and to put the injured part at rest, hence their name. They are not sympathetic filaments, for the phenomenon is observed in skin completely deprived of its sympathetic innervation. Lewis bases his conclusion that the nerves which respond in the ordinary way to pain stimuli are not responsible, upon the diffuse and poorly localized character of the hyperalgesia, and upon the effects of ischemia and of cocaine. The nerve fibers responsible for the hyperalgesia are paralysed by ischemia but are little effected by cocaine. Pain sensations, on the contrary, are affected rela-

tively little by ischemia but are readily abolished by cocaine. He rejects the idea that substances produced at the injured site and diffused through the skin are the cause of the soreness because, if a *small* area is anesthetized with cocaine and an injury produced within it, hyperalgesia does not develop in the surrounding part until after the effect of the anesthetic has passed off.

Dissociation of sensations. In disease, the several modalities of sensation, touch, cold, warmth, and pain may be lost separately; or they may be temporarily dissociated by artificial means as by asphyxia, cocaine or the application of cold. Thus, the cutaneous sensations, touch, cold, warmth and pain are lost in this order when the skin is made ischemic. If it is cocaineized, the appreciation of cold is lost first then follow in order the senses of warmth, pain and touch. Cooling the skin causes first, failure in the response of the cold receptors, then in succession the sensations of touch, pain and warmth are lost. Also, after section of a cutaneous nerve, the area of pain loss is smaller than that of touch, there is thus a boundary zone from which a response to a painful stimulus, such as that of a pin prick, can be obtained but which is insensitive to light touch.

Epicritic, protopathic and deep sensibilities

Head and his associates, from the study of a large number of peripheral nerve injuries, grouped the several sensations into three classes: (1) *epicritic*, (2) *protopathic* and (3) *deep sensibility*. Under *epicritic sensibility* are included light touch over hairless parts, the power of localizing the point touched, the detection of two individual sensations when two points are touched simultaneously, and the appreciation of finer grades of temperature, cool and warm, i.e., temperatures ranging between about 40° and 25°C. *Protopathic sensibility* is a more primitive type of sensation and more widely distributed. It includes pain and the temperature sensations aroused by extremes of heat and cold—above 40° to 50°C. and below 20° to 25°C. In other words, protopathic sensibility possesses a high threshold; but, through the stimulus must be strong in order to arouse a sensation, this once aroused is intense, diffuse, poorly localized and peculiarly unpleasant in quality. These latter qualities of protopathic sensibility are particularly prominent in the absence of epicritic sensibility, which therefore has been considered to exert a restraining influence upon the former. The glans penis possesses only protopathic and deep sensibilities. *Deep sensi-*

bility is aroused by the stimulation of structures in the deeper layers of the skin, and in the muscles, bones and joints. The sensations aroused are, as a rule, well localized; they consist of *pain*, *pressure* and the sense of *position* or *movement* of a part (see also under proprioceptors).

For the purpose of studying these three sensations Head underwent an operation in which his radial nerve and the cutaneous branches of the musculo-cutaneous nerve were severed at the elbow. After the operation there was *complete* loss of cutaneous sensation over the radial half of the back of the hand. Surrounding this was a narrow zone in which epicritic sensibility alone was lost; protopathic was retained. This is due to overlapping of the protopathic innervation of the adjacent unaffected skin area. Over a small triangular area of skin at the wrist the relationship between these two sensations was reversed; protopathic sensibility was lost but epicritic retained. Stopford has since shown that this latter type of dissociation of the two groups of sensations is also characteristic of section of a posterior root—the area of protopathic loss being much greater than epicritic. In Head's experiment evidence of returning sensation (due to regeneration of the nerves) was noticed on the 43rd day after operation when the zone of protopathic sensation was found to have become broader and to have encroached upon the totally insensitive area. The original area insensitive to light touch remained unreduced. Within about six months *protopathic* sensibility had returned over nearly the entire area, yet the extent of the *epicritic* loss remained unaltered. The first signs of the return of epicritic sensation was not observed until a year after the operation and was not complete after the lapse of two years.

Deep sensibility is evidently not mediated by fibers in cutaneous nerves, but by afferent fibers running with the motor branches, for this sensation remained unaffected by the operation. Light pressure could be everywhere appreciated. This is an important point to remember in the investigation of nerve lesions since it shows that crude methods for studying the sensations of touch may fail to reveal any loss. The superficial touch receptors are stimulated alone by light contact with a wisp of cotton or by the pressure of a fine hair, whereas a pressure not very much greater, as with the point of a pencil, will stimulate the deeper lying pressure receptors (Pacinian corpuscles) whose nerve fibers may be intact while those of true touch are destroyed. As a result of these experiments in which dissociation of the three types of sensation were clearly demonstrated Head and his associates concluded that each sensation was mediated by a separate and structurally distinct group of fibers. Unquestionably, a deep sensibility is conveyed by fibers separate from those responsible for cutaneous sensations, but that epicritic and protopathic sensations has each its specific fiber group has been seriously questioned. The work of Erlanger and Gasser and of Ranson appeared to lend support to Head's interpretation. The C fibers of the former

authors were suggested as the possible mediators of protopathic sensation and the A group, of epicritic. Ranson had previously described unmyelinated fibers in the cutaneous nerves which, since they were believed to mediate pain might offer an anatomical basis for the primitive protopathic sensations. The existence of protopathic sensation only in the glans penis and the dissociation of the two sensations, which as shown by Stopford result from section of the posterior roots, also supported Head's conception of two distinct sets of fibers. Experiments by other neurologists, on the other hand, have failed to substantiate this contention (see Trotter and Davies). Some would explain the two classes of cutaneous sensation following nerve section upon the basis of different rates of regeneration of the receptor organs, the terminals of the pain fibers being thought to regenerate first. Fine discrimination, according to Heinbecker, is dependent upon the *number* of active end organs within a given area. The zone of protopathic sensibility surrounding an anesthetic area caused by nerve section is ascribed simply to the presence, in reduced numbers, of intact afferent endings which have overlapped the field of distribution of the sectioned fibers. The recognition of these two types of sensation, whatever may be their anatomical basis, is, however, of distinct value from a clinical standpoint.

Vibration sense. This is the ability to perceive stimuli of a vibratory nature applied to the skin by means of a tuning-fork or other rapidly oscillating instrument. There is some doubt as to the character and situation of the receptors upon which this sense depends. According to some investigators they are present in bone, periosteum and tendons, and are therefore part of the system of deep sensibility; others contend that they are confined to the skin. Pollock has shown that the vibration sense is retained though the superficial sensations (epicritic and protopathic) have been lost, which indicates that it is conveyed by fibers other than those mediating the latter sensations, namely by the deep system. The receptors are probably situated in the subcutaneous tissues or though less likely in the deeper layers of the skin; they are fewer in bone and periosteum. The receptors sensitive to pressure, namely, the Pacinian corpuscles, may be those concerned with the registration of vibratory sensations. Others claim to have obtained evidence indicating that the stretch receptors in neighboring muscles respond to the stimulus of vibration.

THE PROPRIOCEPTORS OF MUSCLES, TENDONS AND JOINTS

The receptors situated in skeletal muscles and in the tendons and joints furnish information to the central nervous system concerning the move-

ments and positions of the limbs and other parts. Afferent fibers carrying this information make up from $\frac{1}{4}$ to $\frac{1}{2}$ of the fibers in a so-called motor nerve. As a result of the messages received by the nervous system, the contractions of individual muscles and groups of muscles are coördinated to produce smooth, finely adjusted and effective movements which would be impossible in the absence of such guidance from the periphery. For this reason the term *kinesthetic* is applied to this group of receptors. A proportion of these afferent impulses arouse no sensation, their information being delivered to centers lying beneath consciousness. To others are due the sensations grouped in the last section under deep sensibility. The receptors in the situations mentioned respond to mechanical stimulation, e.g., pressure or stretch. These types of stimulus are furnished by the strains and stresses set up in the muscles, tendons and joints during muscular contraction.

The sensory endings in the various situations mentioned above are of four main types: (1) *muscle spindles*, (2) *Golgi corpuscles*, (3) *Pacinian corpuscles*, and (4) *free nerve endings*.

(1) *The muscle spindle* is a fusiform body from .75 to 4 mm. long and from 0.1 to 0.2 mm. broad lying parallel to and between the muscle fibers (fig. 330). It is constituted of a bundle of from 2 to 10 muscle fibers (intrafusal fibers) enclosed in a fibrous capsule. The latter is separated from the intrafusal fibers by a lymph space bridged across by delicate septa. The intrafusal fibers differ from the ordinary fibers of the muscle in being smaller and more circular on cross section, and in having a greater number of nuclei and coarser striations. The nerve supply of the spindle is double—afferent and efferent. The afferent enters the spindle about its center, the latter more toward one or other end. The efferent fibers are distributed to end organs in the intrafusal fiber which resemble but are not identical in structure with the motor end plates of ordinary muscle fibers. Upon entering the spindle and losing its myelin sheath and neurilemma, an afferent fiber may end in one or other of two ways. (a) Some become flat and ribbon-like and wind themselves in rings or spirals (*annulo-spiral endings*) about the intrafusal fibers. (b) Others ramify upon the latter's surface in a manner suggesting a spray of flowers ("*flower spray*" ending of Ruffini).

(2) *The Golgi corpuscles* (fig. 330) are situated in tendons and consist of a bundle of tendinous fibers surrounded by a lymph space and enclosed within a fibrous capsule. Afferent nerve fibers

enter the organ near its center and ramify upon its constituent fibers. Tension is the adequate stimulus for these receptors.

(3) *The Pacinian corpuscles* are oval bodies composed of concentric laminae, like the "skins" of a sectioned onion. The afferent fiber penetrates to the center of the corpuscle. Pressure with elongation of the organ and consequent stretching of the nerve ending is the adequate stimulus. These receptor organs are found in tendons, joints, periosteum, especially beneath tendinous insertions, in fasciae covering muscles and in subcutaneous tissues (fig. 329). They are also found in the mesentery. The structure of these receptors appears to be such that a mechanical stimulus such as stretching, pressure, etc., induced by muscular action will be applied most effectively to the naked axis cylinder within its center.

(4) *Bare nerve endings* lie between the muscle fibers, in tendons and in the fasciae and joints. They mediate deep pain.

FIG. 330. 1. Golgi ending in tendon; 2. intrafusal fiber showing, a, muscle flower spray and b. annulo-spiral endings.

THE RESPONSES OF CERTAIN SKIN AND MUSCLE RECEPTORS

When non-polarizable electrodes are placed upon a mixed nerve of an intact animal at rest or upon a posterior root, a continuous stream of action currents can be recorded. These impulses of the "resting" nerve have a relatively low frequency—from 3 to 5 per second. They arise mainly from proprioceptors of muscle and tendons. The mere passive movement of the limb supplied by fibers entering the posterior root under investigation causes a prompt and pronounced rise in the impulse frequency. Light pressure upon the skin or even brushing the hairs also causes a rise in frequency as the result of stimulation of skin receptors. Adrian and his associates have recorded the afferent impulses from the frog's sciatic set up by stretching the gastrocnemius, from a nerve fiber supplying a single touch receptor of

the frog's skin, and from the plantar digital nerve of the cat during the stimulation of the receptors of pain, touch or pressure in the skin of the toe pad.

When the receptors in the skin of the toe pad of the cat were stimulated by light contact or pressure the record taken from the plantar digital nerve showed a rhythmical discharge of impulses having a frequency of 150 per second. The frequency rose with an increase in the degree of pressure. Adrian and Umrath were able to locate a single Pacinian corpuscle and stimulate it by pressure with a hair or a fine glass rod. The impulses were recorded by means of an amplifier system in conjunction with a Matthews oscillograph. Pressure upon the end organ caused a discharge of impulses at a rate as high as 100 per second. A group of corpuscles lie beneath the flexor muscle of the toe; movement of the phalangeal joint crossed by the muscle stimulated the receptors and caused a discharge of impulses. Temperature changes failed to excite. The response of a single muscle spindle to stretch was also investigated by Adrian and Zotterman. They employed the sterno-cutaneous muscle of the frog which arises from the abdominal wall and is inserted into the skin over the chest. The entire muscle contains only 3 or 4 muscle spindles, and by the successive removal of portions of the muscle a preparation containing a single spindle with its nerve fiber intact was obtained. A sudden stretch (by means of a weight) applied to the muscle caused a rhythmical discharge of impulses along the nerve. The end organ apparently obeys the all or none law since increasing the strength of the stimulus above the threshold did not increase the *magnitude* of the electrical response. The *frequency* of the responses varied, however, directly with the intensity of the stimulus from 5 to 100 per second. A higher rate than this (300 per second) was obtained from a single touch receptor of the frog's skin by Adrian, Cattell and Hoagland, a blast of air being employed as the stimulus.

Matthews employed a small extensor muscle situated upon the outer side of the middle toe of the frog. This muscle contains a single muscle spindle. The afferent impulses were recorded by means of an amplifier and oscillograph from a small branch of the peroneal nerve supplying the muscle. The muscle spindle was stimulated by loading the muscle at various rates and with weights of different amounts. It was found that: (a) the frequency of the impulses set up were roughly proportional to the logarithm of the load, (b) at 16°C. the maximum impulse frequency

obtainable was 290 per second. That is, each impulse followed its predecessor at an interval of only 0.0035 second. It follows therefore that each impulse traveled within the relative refractory period (0.01 second) of the preceding one. For this reason, some reduction (15 to 20 per cent) in the magnitude of the action potential waves occurs when they follow one another in rapid succession. Upon altering the temperature of the preparation the maximum frequency of the impulses varied in the same way as did the refractory period of nerve; that is, raising the temperature which has the effect of shortening the refractory period of nerve also shortens the interval between the impulses set up by maximal stimulation of the muscle spindle. (c) Passive stretch is an adequate stimulus to the muscle spindle provided the stretching force rises to its maximum at a sufficiently rapid rate. That the impulses recorded from the afferent nerve originated in the spindle was evidenced by the fact that when it was rendered functionless (by constricting it tightly with a thread) no impulses could be set up thereafter by stretching the muscle. It has been further shown by Matthews for mammalian muscle that though the two elements of the spindle ("flower spray" and annulo-spiral, p. 805) are stimulated by *passive* stretch, each behaves differently to *active* contraction of the muscle. The responses of the "flower spray" endings cease during contraction which apparently relieves the strain upon them. Those from the annulo-spiral endings also cease if the contraction is submaximal. With a supra-maximal contraction, however, they increase in frequency, due then, it is believed, to a contraction of the intrafusal fibers. The Golgi endings in tendon respond to stretch whether passive or induced by contraction of the muscle.

Adaptation

The rhythmical discharge of impulses set up by stimulation of a receptor gradually diminishes in frequency and may soon cease entirely, though the stimulus continues to be applied at its original intensity. If, for example, the touch receptors of the cat's toe pad are excited by resting a glass disc lightly upon the skin a burst of impulses occurs at high frequency for from $\frac{1}{10}$ to $\frac{1}{8}$ second, but have entirely ceased by the end of $\frac{1}{4}$ second. After this, pressure exerted upon the disc is followed by a second series of impulses which again comes to an end though the pressure is maintained unchanged. This phenomenon is spoken of as *adaptation* (fig. 331). The gradual numbing of sensation to a constant stimulus is a common experience. We speak of "becoming accustomed" to some or other environmental change which initially caused a very definite effect. The olfactory endings, for instance, soon become adapted to the action of most odorous substances, and a

light object placed upon the hand soon becomes imperceptible. We do not feel the contact of our clothes; the ticking of a clock after a time is not heard; and a hot bath feels much hotter when one first enters it than after a short period of immersion. The receptors of the retina also undergo rapid adaptation, failing to respond after a brief period of stimulation. For this reason a small moving object is more readily perceived than a stationary one, and when one directs his attention to a motionless object the eyeballs are kept constantly moving in order to stimulate the receptors intermittently.

Adaptation should not be confused with fatigue. It occurs to the same extent whether the frequency of discharge is slow or rapid; if it were a fatigue phenom-

FIG. 331. Adaptation. Graph of response during first second after sudden loading with a large load. 100 gm. Temperature 14 C. (after Matthews).

enon it should of course be more evident at rapid discharge rates. Furthermore, the excitability of the adapted end organ to a fresh stimulus is not reduced, and whereas fatigue is affected by oxygen lack, adaptation is not. Adaptation is a property common to receptors whether of skin, muscle, viscera or special sense organs. Its rate of development, however, is different for the several types of end organ, being very rapid for those of touch, slower for those of pressure and warmth and still slower for those of pain and for the muscle spindle. Receptors whose function it is to record sudden changes in the external environment adapt rapidly. This is necessary in order that, having responded to a given environmental change and conveyed their message to the central nervous system, the receptors shall again be ready to respond to another stimulus, and also that information received from receptors stimulated successively shall not be confused. We are aware for instance, of the movement of a light

object over the skin since successive touch receptors respond instantly to the stimulus and adapt rapidly. If rapid adaptation did not occur, that is, if the discharge of impulses outlasted to any appreciable extent the duration of the external stimulus, the subsequent stimulation of neighboring receptors would result in a diffuse ill-defined sensation. It is necessary, on the other hand, for the muscle spindle to adapt very slowly, since upon this receptor depends in part the reflex maintenance of a continued tonic contraction of postural muscles. It would seem requisite, on the other hand, that proprioceptors giving information concerning the *movements* of muscles and joints should adapt rapidly. There is little information, however, upon this point. The proprioceptors of the carotid sinus and aorta adapt slowly, those excited by inflation of the lung also have a slow rate of adaptation. Sudden forcible inflation of the lung, for example, causes a burst of impulses at the rate of 150 per second; by the end of the first second the frequency has only fallen to 115 per second.

A comparison of receptor and nerve fiber responses

In general the nerve fiber and the end organ (or rather the nervous element of the latter) behave similarly. Both require for excitation a stimulus of a certain minimal strength and this must rise to its maximum value at a certain rate and have a certain minimal duration (p. 781). Both obey the all or none law and have absolute refractory periods of about the same duration. There are certain differences, however, between the responses of the two structures, and some of these have already been pointed out. The sense organ possesses a low threshold for one type of stimulus whereas the nerve fiber responds unselectively to various types. The later stages of recovery (relative refractory period) of the end organ are slower than those of the nerve fiber. The sense organ also differs from the nerve fiber in giving a rhythmical response to persistent stimulation. When a constant current of moderate strength is sent into a nerve a single impulse results, the refractory phase follows and though the current continues to flow a second response does not occur when the nerve recovers. If the stimulus, however, is very intense a short series of impulses may result. The apparent differences in response between the nerve fiber and end organ to persistent stimulation is therefore only quantitative. The nerve adapts rapidly, the sensory endings slowly. As a matter of fact the touch receptors adapt almost as rapidly as the nerve fiber itself (fig. 332). The rhythmical nature of the end organ response is thought to be due to the stimulus causing a

state of persistent depolarization in the surface film of the non-medullated ending within the receptor. The depolarized section of nerve then acts as a constant stimulus to the rest of the fiber. Lillie's iron wire model (p. 791), for instance, will respond rhythmically if the protective film of oxide is prevented from forming upon a terminal section of the wire. The maintenance of this part in a depolarized or active state causes a series of electrochemical reactions to be transmitted down the wire, the protective film forming upon the length of the wire after each wave has passed. Adrian also found that when the end of a nerve is injured rhythmical responses of high frequency are set up. These are probably the result of increased permeability of the damaged surface film, which therefore remains in a permanently depolarized state. These observations suggest that a mechan-

FIG. 332. Showing the response of nerve fiber and of different types of receptor to a continued stimulus. Adaptation is most rapid in the nerve fiber and slowest in the muscle spindle (from Adrian, *The Basis of Sensation*, Christophers, London).

ical stimulus applied to a sense organ causes deformation of its nerve ending with the production of analogous changes in the surface film which, persisting for a short space of time, cause the rhythmical discharge.

THE INTENSITY AND QUALITY OF SENSATION. SPECIFIC NERVE "ENERGIES"

It has already been pointed out (p. 786) that the form and magnitude of the electrical response and so presumably of the nerve impulse are not altered by increasing the intensity of the stimulus applied to a receptor organ. So far as is known the only effect of raising the intensity of the stimulus is to increase the frequency of the impulses discharged. *Intensity of sensation* is believed, therefore, to depend upon the number of impulses

reaching the sensorium per unit of time. The number of impulses reaching the sensory areas of the brain in a given time is dependent not only upon the frequency of the impulses arriving by each fiber but also upon the number of fibers involved. What may be termed the *massiveness* of the sensation is probably largely dependent upon the latter factor.

To what are due the different *qualities of sensation*? Is each type of sensation, e.g., touch, pain, sight, hearing, etc., mediated by a specific type of nerve fiber, that is, one with a distinctive type of end organ and which conveys impulses to a particular region of the brain? However stimulated does each type of end organ always produce the same quality of sensation? On the other hand, is the type of sensation dependent upon the induction in non-specific nerve endings of some change characteristic of the type of stimulus applied, the characteristic effect of the stimulus being then conveyed as a message to consciousness? The first view, which is generally accepted, is spoken of as the *doctrine of specific nerve energies*. The principle was enunciated in 1838 by Johannes Müller, though it had previously been suggested by Sir Charles Bell of Edinburgh. It was extended by Helmholtz to apply to the different qualities embraced within a single type of sensation, as in his resonance theory of hearing—the appreciation of variations in pitch being dependent, it was claimed, upon the situation in the cochlea of the particular end organs which were stimulated. Also, in Young's theory of color vision the appreciation of the different primary colors was attributed to the presence of distinct sets of fibers.

Evidence for the existence of specific nerve fibers can be derived from common experience. Mechanical stimulation of the retina, for example, causes a visual sensation only; a mechanical stimulus applied to the ear produces a sensation of sound. The presence in the skin of definite "spots" for touch, pain, pressure, etc., also points to the different cutaneous sensations being dependent upon the adequate stimulation of specific endings, each of which transmits its message to the central nervous system along a definite pathway. The stimulation of a touch spot gives rise to a feeling of touch, of a warm or cold spot to a sensation of warmth or cold, and the stimulation of a pain spot to pain. The specific nature of the touch receptors in the skin of the frog is indicated by the experiments of Adrian, Cattell and Hoagland; these receptors cannot at any rate give rise to pain,

for when they were stimulated to discharge impulses at the maximum rate (300 per second) there was no indication that the sensation was painful. A stimulus which would cause an impulse discharge of this frequency from a pain ending would certainly cause severe pain. Comparable results were obtained from the touch receptors at the roots of the hairs in the guinea pig. It has also been shown that a pressure receptor (Pacinian corpuscle) cannot give rise to pain nor is it stimulated by temperature changes.

Granted that specific fibers do exist, there is the further question,—are the messages emitted by the various end organs and transmitted along the nerve fibers identical, and do the qualities of sensation depend solely upon the connections which the respective fibers eventually make with cells in the brain? Or, on the other hand, does the specific function of the fiber depend upon some distinctive character of the impulse which it transmits? For example, do the impulses set up by stimulating a pain ending differ in some significant way from those originating in a touch receptor?

Though in general the impulses, whatever their origin or whether motor or sensory, are closely similar, certain quantitative and qualitative differences do exist. Erlanger and Gasser (p. 789), for example, showed that the axon potentials of different fibers had different conduction rates and amplitudes. Adrian and others have shown differences in the frequency of the impulses. Impulses may therefore differ from one another in (a) conduction rate, (b) magnitude or (c) frequency. Some such differences as these might possibly serve as a basis for the several qualities of sensation.

It seems unlikely that differences in frequency of the impulses can be a factor, since the impulses aroused by touch may have as high a discharge rate as those aroused by pain.³ The fibers supplying the receptors

of the skin are of smaller diameter than those going to muscle proprioceptors, which indicates that the former have slower conduction rates than the latter, and Matthews actually found that the impulses set up by stimulating a muscle spindle (which are supplied by alpha fibers of the A group, p. 790) had a higher conduction rate than those originating in a touch receptor (which are probably supplied by beta fibers of the A group). Again, the impulses set up by the application of heat to the skin have a slower conduction rate than those originating in a touch receptor, while pain impulses, in part at least, are believed to be transmitted over fibers (C group) having the slowest conduction rate of all. The form or attitude of the action potential waves recorded from one type of fiber may also show certain differences from those traveling over another type.

Nevertheless, there is little reason to believe that any of the differences mentioned—frequency, conduction rates, form or amplitude⁴—play a major rôle in determining the qualities of sensation. Qualities of sensation are determined by the particular type of end organ stimulated (which is specially adapted to respond to one type of stimulus) and are ultimately dependent on the nerve cells in the brain where the impulses arrive. As someone has expressed it, if impulses arising in the retina were directed to the temporal lobe and auditory impulses to the occipital lobe we should hear the lightning and see the thunder. The characters of the messages themselves, e.g., their conduction rates or amplitude, may however and probably do play their part in aiding the central nervous system to sort out the impulses from various sources and direct them to their destinations. Within the central nervous system each afferent fiber makes connections with several nerve cells. Thus several alternate pathways exist, and the slight differences in the characters of the impulses may be factors determining the course which shall be taken.

³ The impulses in the optic nerve during retinal stimulation have about the same frequency as those from a cutaneous receptor.

⁴ Another conceivable possibility is that impulses from different receptors might show characteristic groupings which might serve as a basis for sensation, but there is no evidence that such occurs.

CHAPTER LXV

REFLEX ACTION

The point of contact through which physiological continuity is established between two neurons is called the *synapse*. The axon of the neuron divide into numerous filaments which terminate in small button-like expansions known as end-feet (*pieds* or *boutons terminaux*) which are applied to the surface of the body or dendrites of another neuron (fig. 333). A single anterior horn cell shows several hundred (up to 1300) such contacts. It is generally taught that no structural continuity exists between neurons, but merely contact in the manner described. The fact that when a neuron is injured Wallerian degeneration (p. 779) does not extend beyond its boundaries to involve a neighboring neuron supports this conclusion. The end feet themselves quickly show degenerative changes after the axon has been interrupted; within from 24 to 72 hours they become swollen and at the end of about 120 hours undergo granulation and disintegration. The absence of protoplasmic continuity between two neurons implies that something in the nature of a surface film, though this be no more than a single molecular layer, is interposed. Such a film will provide a site for the development of surface phenomena, e.g., the formation of an electric double layer upon which the peculiar properties of the synapse probably depend. The synapse might therefore constitute a point of raised resistance—a higher threshold than that of the nerve fiber itself—which the impulse would need to cross or “step over” in order to reach another neuron. Or the synapse might provide a mechanism through which a *fresh* impulse is set up, rather than that it simply interposed new conditions in the path of the original one.

THE CHARACTERISTIC FEATURES OF REFLEX ACTION

Spinal reflex action shows several phenomena which have been studied intensively by Sherrington and his associates and have been generally considered to indicate a basic difference between conduction over reflex arcs and conduction in the nerve fiber. These special features, which will be described in this chapter, have been attributed to the synapse interposed between contiguous neurons. However, as an outcome of recent research it is becoming evident that the

peculiar characteristics of reflex conduction upon which such stress has been laid in the past are manifestations of special modifying conditions of a non-essential nature at the reflex center and should not be taken to imply that the processes underlying the two types of conduction differ from one another in any fundamental way (see p. 821).

(1) *Summation*, temporal and spatial (See p. 811).

(2) *One-way conduction*—centripetal in the afferent and centrifugal in the efferent limb—as compared with two-way conduction in nerve fibers. The synapse may be compared to a valve or a gate which opens only one way. The irreversibility of conduction in the reflex arc was demonstrated in the early part of the 19th century by Bell and Magendie. The former (1811) showed that stimulation of the anterior roots cause muscular contraction, but no apparent effect followed stimulation of the posterior roots. Magendie (1822) found that stimulation of the posterior roots caused pain. These observations have been embodied in the so-called Bell-Magendie law which states that the anterior root fibers are purely efferent, those of the posterior roots purely afferent.

One-way conduction is not, however, an unalterable property of the synapse, for it is abolished by lowering the temperature of the spinal cord by a few degrees. It has been shown by Toennies, for example, that if the cord is cooled, stimulation of a dorsal root causes a discharge of impulses from the center which travel peripherally over a certain proportion of the fibers composing other dorsal roots, that is, antidromically (p. 235). Barron and Matthews have also found that cooling the cord causes muscular twitchings, and that each twitch is accompanied by a discharge of impulses along sensory root fibers.

(3) *Slower speed of conduction*, as measured by the latent period between the application of the stimulus to the afferent limb of the reflex arc and the response of the effector organ (e.g., contraction of a muscle). (p. 812)

(4) *Grading of the reflex response*. Variations in the strength of the stimulus cause corresponding gradations in the reflex response. When stimuli of gradually increasing intensity are applied in suc-

pression to a motor nerve the muscle shows step-like increases in response as a result of more and more nerve fibers being excited and of an increasing number of muscular units being brought into play, but after this an increase in the strength of the stimulus causes no greater effect ("all or none" principle, p. 785). In the case of the reflex response, increasing the strength of a single stimulus beyond that which brings all the afferent fibers into play may cause a further increase in the response of the muscle.

(5) As a result of a repetitive discharge from the center ("after discharge," p. 814) there is a lack of correspondence between (a) the moment of cessation of the stimulus and the termination of the response of the effector organ, and (b) the rhythm of the stimulus and that of the muscular response.

FIG. 333. Diagram showing "end feet" (*pieds terminaux*) making contact with the body of a nerve cell.

(6) *Greater variability in the threshold value* of the stimulus in the case of the reflex arc. The response to a given stimulus is influenced by conditions which do not come into play in the case of nerve fiber conduction, e.g., facilitation, recruitment, occlusion, etc. These will be considered later.

(7) *Susceptibility of reflex conduction to fatigue*, whereas nerve trunks are almost indefatigable.

(8) *Much susceptibility of reflex conduction to oxygen lack, anesthetics, shock, etc.* This is evidently due to the presence of the nerve cell in the conducting pathway. Nerve cells have a much higher metabolism than nerve fibers (p. 795) and reflex excitability is abolished if the centers are deprived of oxygen for a short period. The cells of the cerebral cortex are irreparably damaged if deprived of their blood supply for 5 minutes or so; in man deprivation of blood for even half a minute

may cause injury. The centers of the brain stem survive for a longer period—from 25 to 35 minutes, and the spinal centers for from 40 to 60 minutes. The autonomic centers are also relatively resistant to oxygen lack. According to Kabat, the resistance of the brain in very young animals (puppies up to 4 months of age) to circulatory arrest is much greater than is the adult brain. In deep *anesthesia* many reflexes are completely abolished, whereas nerve trunks remain excitable and may even respond to stimulation after an animal has been killed by an overdose of anesthetic. Ether vapor or other anesthetics applied *directly* to the nerve, however, quickly abolishes its excitability.

Some of the special features of reflex conduction mentioned above will be dealt with in more detail in the following pages. Certain other characteristic features of reflex action will also be considered.

Summation. The central excitatory state

Temporal summation. Though a single stimulus of a certain strength may, when applied to an afferent nerve or receptor organ, be unable to cause reflex contraction of a group of muscles, a response occurs if a series of such stimuli is applied to the nerve in rapid succession. This phenomenon is referred to as *temporal summation*. The shorter the intervals between the stimuli, which singly are inadequate, the greater is the reflex response; if separated by intervals greater than about 20 msec they are ineffectual. Such a result is best explained upon the assumption that each inadequate stimulus produces an excitatory state within the center; this state, though itself incapable of causing a discharge down the motor neuron (motoneuron), persists for an appreciable time and can sum with central excitatory states (C.E.S.) produced by the succeeding stimuli (see summation of inadequate stimuli, p. 781). Through such summation, the central excitatory state is raised to threshold value and a discharge occurs over the efferent neuron. A single impulse is rarely, if ever, able to give rise to a C.E.S. of threshold value. Temporal summation is well exemplified in the *scratch reflex* shown by the spinal dog (p. 829). This reflex, which consists of rhythmical scratching movements of the hind limb when the skin of the back is stimulated, cannot be elicited by the application of a single induction shock or even by two shocks unless they are very intense. The reflex is readily elicited by a series of rapidly repeated weak stimuli.

Sometimes the response does not occur until after the fortieth repetition (Sherrington). A single *mechanical* stimulus applied to the skin (e.g., plucking a hair, a pinch, etc.) may elicit the reflex, but under such circumstances it is probable that the receptor organ discharges a series of impulses (see p. 807).

In experiments involving direct stimulation of the oculomotor nucleus Lorente de N6 observed that increasing the interval between inadequate stimuli to more than from 0.1 to 0.2 msec. greatly reduced the summation value. The maximum summation effect was obtained when the stimuli were simultaneous. Since in these experiments the length of the interval at which any significant summation effect was observed is shorter than the relative refractory period of the afferent nerve fiber, considerable doubt has been raised as to the importance of temporal summation at any individual synapse. However, since the impulses in their course to the reflex center pass through internuncial neurons and are delayed in their passage through each synapse by from 0.5 to 2.0 msec., the anterior horn cell may be maintained in a state of subliminal excitation for a period up to 20 msec. A second inadequate stimulus applied to the afferent nerve during this time will raise the central excitatory state to threshold value.

Spatial summation. If two subthreshold stimuli are applied simultaneously, one to each of two afferent nerves, summation occurs and a response results. This type of summation, which is of essential importance in central excitation, is spoken of as *immediate spinal induction* or *spatial summation*. Allied reflexes mutually support or reinforce one another through such an effect. This therefore constitutes one type of *facilitation*. Immediate induction can also be readily demonstrated in the scratch reflex. When two subthreshold stimuli are applied within the receptive area of the reflex but about 10 cm. apart a response follows. Such a result, taken in conjunction with other observations which will be considered presently, indicate that the two afferent pathways converge upon and make connections with the same motoneurons.

Refractory periods

The nervous centers show an absolute and a relative refractory period, as well as a phase of supernormal excitability. The length of the absolute refractory period as observed by Eccles for the motoneurons of the flexion reflex is 2.5 msec. and from 10 to 15 msec. for the period of relative,

refractoriness. A lower value, namely 0.1 msec. was obtained by Lorente de N6 for the motoneurons of the more rapidly acting eye muscles. The refractory period is determined by applying strong stimulus to the undivided motor nerve of the reflex, and thus sending a volley of impulse backwards, that is, antidromically, into the spinal center. The antidromic volley causes discharge of the center just as though it had been stimulated through the afferent nerve. The succeeding interval during which the reflex cannot be elicited by stimulating the afferent nerve is the absolute refractory period. This is followed by a period of subnormal excitability—the relative refractory period.

Reflex conduction time

The time elapsing between the stimulation of the afferent nerve or receptor and the response of the effector organ is called the *total latent period* of the reflex. If from this be subtracted the time which the impulse would take in traveling over the afferent and efferent fibers (which conduct at rates from 80 to 100 meter per second) the time taken by the impulse to pass through the cord is obtained.¹ This is called the *central or reduced reflex time*. In the table given below the total latent period is 10.4 msec. and the total time of the peripheral pathways is 6.5 msec. leaving 3.9 msec. as the central reflex time. Since the length of the central pathway is only a small fraction of the length of the peripheral path while the central reflex time is nearly $\frac{1}{2}$ the total time, it is clear that the conduction rate through the center must be relatively very slow. The delay presumably occurs at the synapse and is attributed to the time required to build up the excitatory state to threshold value.

Total latent period.....	10.4 m. sec.
Time for passage of impulses in 13.8 cm. of afferent nerve at 31.6 meters per second...	4.4 m. sec.
Time for passage of impulses in 19.5 cm. of efferent nerve at 93 meters per second.....	2.1 m. sec.
Total time for peripheral path.	6.5 m. sec.
Therefore central reflex time (synaptic delay).....	3.9 m. sec.

—Modified from Creed, Brown,
Eccles, Liddell and Sherrington.

¹ If the time of arrival of the action current at the end of the efferent nerve is recorded the latency of the muscular response need not be considered.

When the interval between two stimuli applied to an afferent nerve is sufficiently brief the latent period of the response caused by the second stimulus is shorter than usual. The shorter latency cannot be attributed to a reduced conduction time in the peripheral nerve fibers; it must be central in origin, i.e., at the synapse. Now, the excitatory state rises to a maximum during a measurable time and declines again gradually. The reduced latency of the second volley of impulses is therefore attributed to their reaching the synapse before the effect of the first volley has disappeared; therefore a shorter time is necessary for building up the C.E.S. to threshold value. The synaptic delay under these circumstances may be reduced to 0.5 msec.

The delay is also greatly reduced by increasing the strength of the stimulus and may then be so slight that the conduction rate over the arc as a whole approaches that over nerve trunks.

Successive induction

This term is applied to the facilitation which one reflex exerts upon another immediately succeeding it. Successive induction may be *positive* or *negative*, that is, the second reflex reaction may be of the same sign as the first or of opposite sign. An example of positive successive induction is the augmentation of the scratch reflex which follows the successive stimulation of two separated points in the skin, as by rolling a spurred wheel over the surface. A parasite moving over the skin will exert a similar effect. Negative spinal induction is seen in rhythmical or alternating reflexes such as stepping, the shake reflex of the head or the biting reflex. For instance, the flexion reflex (contraction of flexors and relaxation of extensors of the limb) favors a succeeding extension reflex (contraction of extensors and relaxation of flexors) which in turn lowers the threshold for the next flexion reflex.

In the spinal animal (p. 828) spontaneous automatic stepping or scratching movements may occur which under favorable conditions persist for several minutes. Automatic stepping movements of the hind limb of the cat may persist even under deep anesthesia and after the opposite half of the cord of the segment supplying the limb has been destroyed. The reflex alternating movements are not abolished by deafferentation of the limb (section of posterior roots). The perpetuation of the rhythm is therefore not due to impulses arising in the contracting muscles; it is central (spinal) in origin.

Rebound

Allied to negative spinal induction is the phenomenon known as *rebound*. When, for instance, during the elicitation of a reflex, inhibition is induced by the stimulation of an afferent nerve, augmentation of the reflex occurs when the inhibitory stimulus is withdrawn (fig. 334). The rebound has a long latent period occurring about 0.2 second after the withdrawal of the inhibition. Sometimes the mere cessation of the stimulus which excited the reflex is sufficient, without inhibition, to cause rebound. It is most readily elicited in the crossed extension reflex of a decerebrate preparation. It is elicited with difficulty in the spinal animal. It is easily inhibited. It

FIG. 334. Between *c* and *c'* the stretch-reflex of vastocrureus is inhibited by faradization of the peroneopliteal nerve of the same side. Note the inhibition and the further fall, "post-inhibitory notch" after *c'*. The post-inhibitory notch is followed by considerable rebound which in turn is inhibited at \uparrow by gentle traction on biceps femoris of the same side (from Creed, Denny-Brown, Eccles, Liddell and Sherrington, *Reflex Activity of the Spinal Cord*, The Clarendon Press).

appears after the silent period of a tendon jerk (p. 823) and, under certain favorable conditions, is followed in turn by inhibition and this again by rebound. Such a series of inhibitions and rebounds following the sudden stretching of a tendon and giving rise to automatic jerking movements is spoken of as *clonus*. The cause of rebound is not known with certainty. It is not due to proprioceptive impulses, since deafferentation of the muscle does not abolish it.

One explanation which has been offered is, that when the inhibitory stimulus is applied, excitatory afferent fibers as well are stimulated but their effects are masked by those of the inhibitory fibers. After withdrawal of the stimulus the persistence of the "after discharge"

of excitation beyond the inhibitory "after action" accounts for the augmented contraction. In certain rhythmical reflexes such as biting, rebound and negative successive induction apparently act together to increase the force of a contraction following a phase of inhibition. For example, electrical or mechanical stimulation of the gums or palate of a decerebrate preparation causes inhibition of the closers of the jaws (temporals and masseters), and contraction of the jaw-openers (digastrics). Immediately upon cessation of the stimulus, the jaw-closers contract powerfully. Thus, a rhythmic chewing reflex tends to keep itself going, so long as there is any material between the jaws upon which to bite (Sherrington).

After discharge

The discharge of impulses from the reflex center and the consequent prolongation of the reflex response after the stimulation of the afferent nerve or receptor has ceased is called *after discharge* (fig. 335). For example, the crossed exten-

FIG. 335. Flexion reflex, showing *after discharge*. The duration of the stimulus is indicated by the pair of nearly vertical lines (after Sherrington).

sion reflex of the dog (extension of knee, ankle and hip following stimulation of the afferent nerve of the contralateral limb) may have, if the stimulus is very intense, an after discharge of a second or more. In other reflexes, e.g., the flexion and scratch reflexes, the after discharge is much shorter than this (60 to 70 msec.). After discharge is spoken of by Sherrington in a figurative sense as reflex "momentum." Increase in the strength or duration of the stimulus lengthens the after discharge. Increase in the intensity of the stimulus has a relatively greater effect upon the duration of after discharge than upon the amplitude of the contraction; after the latter has been increased to the maximum further strengthening of the stimulus lengthens the after discharge. After discharge is readily inhibited.

As a result of the after discharge from the spinal center a single stimulus applied to an afferent nerve is followed, not by a single twitch as when the motor nerve is stimulated, but by a series of twitches, an incomplete tetanus or even a complete tetanus. When a series of stimuli at a rate under

50 per second are sent into an afferent nerve the rhythm is just perceptible in the myogram whereas in the tetanus caused by direct stimulation of the motor nerve at the same rate the individual contractions are clearly visible. The smoothing out of reflex rhythm is due to the after discharge of impulses following each main volley, the tension of the muscle between the latter is thereby sustained.

After discharge is the result of the persistence and gradual subsidence of the excitatory state built up in the reflex center by the afferent nerve stimulation and the consequent repetitive discharge of impulses along the efferent fibers. The most probable explanation of the prolonged discharge is the one proposed by Forbes, namely that impulses are set up in certain long internuncial circuits and owing to the length of the course over which they must travel are delayed in their arrival at the motoneurons. It is unlikely that the asynchronous arrival of impulses at the center, due to different conduction rates of the fibers composing the afferent nerve or of variable delays at synaptic junctions, plays any important part; the after discharge is too long to be accounted for in these ways. The arrival at the center of impulses set up by the contracting muscle itself is of minor importance. If the afferent impulses from the muscle are blocked by sectioning the posterior roots (deafferentation) the after discharge is reduced though not abolished; it is therefore dependent, in part only, upon the re-excitation of the center by proprioceptive impulses.

Recruitment

Many reflexes gradually increase to a maximum when a stimulus of *unaltered* intensity is merely prolonged. This is due to the activation of a progressively greater number of motoneurons. The phenomenon is called *recruitment* and is figuratively spoken of as "*inertia*" by Sherrington. As already mentioned, "after discharge" is referred to as reflex "momentum." Both features neither of which is in evidence when the motor nerve is stimulated directly, obviously must give smoothness to reflex action. Recruitment is more easily demonstrated in decerebrate than in spinal preparations; it is well seen in the crossed extension reflex but not in the flexion reflex (p. 819). It is also seen in inhibitory reflexes, i.e., prolongation of inhibitory stimulus of constant strength causes the inactivation of an increasing number of motor neurons.

Irradiation

When the strength of a stimulus applied to a receptive area is gradually increased the central excitatory process spreads to a progressively greater number of motoneurons. As a consequence, additional muscle groups take part in the reflex response. The phenomenon is called *irradiation*. The impulses do not spread indiscriminately to all the motoneurons within a given radius of the point of entry of the afferent fibers; on the contrary, owing to the variability of the resistance at different synapses they are directed along selected paths. The synapses at the motoneurons in close proximity to the afferent terminals have the lowest threshold, but as the strength of stimulus is increased impulses spread farther afield and excite the neurons of adjacent and ultimately of more remote segments. For example, a weak stimulus applied to the sole of the hind paw of a decerebrate animal causes flexion of the ankle alone; upon gradually increasing the strength of the stimulus the knee flexes, then the hip (flexion reflex); later, extension of the crossed hind limb occurs (crossed extension reflex); extension of the ipsilateral forelimb follows and finally flexion of the contralateral forelimb. Besides the soles there are six other areas from which irradiation can be demonstrated very easily. These are the palms, the pinnae, the snout and the tail. The final attitude assumed when a stimulus of suitable strength is applied to the sole or to one of the other reflexigenous areas just mentioned is spoken of as a *reflex figure* (see fig. 336.) The spread of the irradiation (march of the reflex figure) in all cases follows a finite order. Upon stimulation of the pinna the order of spread is:—neck and ipsilateral forelimb, ipsilateral hind limb, contralateral hind limb, contralateral forelimb. The order upon stimulation of the hind limb (paw) is:—ipsilateral hind limb, contralateral forelimb, contralateral hind limb, ipsilateral forelimb.

It will be noted that only those muscles which contract synergically, that is, those which combine to effect a purposeful coördinated act, are activated. Muscles whose action is antagonistic to these are inhibited. The reaction which results corresponds to that which would occur from stimulation of the intact animal. Thus a painful stimulus of the hind paw causes withdrawal of the injured part, the other limbs reacting at the same time to support the body and move it from the stimulating agent. The reflex response is therefore quite

different from the response which would result from stimulation of an anterior nerve root—all muscles to which the fibers of the root were distributed would, of course, be activated.

Irradiation is reduced by spinal shock, anesthetics or diminished blood supply to the spinal centers. It is greatly increased by the action of such convulsant poisons as strychnine and tetanus toxin, which cause a general lowering of synaptic resistance; even a weak stimulus may then cause contraction of practically all the muscles of the body, antagonists as well as synergists.

FIG. 336. Reflex figure. A, position of animal after decerebration; B, change in attitude from A caused by stimulation of left hind-foot; C, change in attitude caused by stimulation of left pinna; D, attitude resulting from stimulation of left fore-foot (after Sherrington).

Fractionation of the reflex center

When an afferent nerve is stimulated by a faradic current of *gradually increasing* intensity the tension developed by the reflex contraction increases to a point after which increase in the strength of the stimulus fails to augment the reflex tension. The limitation is not simply due to all the motoneurons of the reflex having been excited, for direct stimulation of the motor nerve causes a development of tension greatly in excess of that resulting from the stimulation of the single

afferent nerve. It is concluded that under the ordinary conditions attending reflex action, a single afferent nerve when stimulated activates only a fraction of the motoneurons supplying a given muscle. The size of the fraction of the motoneurons governed by the afferent nerve varies under different conditions; it is reduced by fatigue, oxygen lack, anesthesia, etc., and increased by the administration of a small dose of strychnine. Even under the most favorable conditions, however, the number of motoneurons excited through a single afferent nerve is not more than a fraction of those which can be excited by stimulating the motor nerve.

TABLE 76

MUSCLE	AFFERENT NERVE STIMULATED	MAXIMUM REFLEX TENSION	MAXIMUM REFLEX TENSION IN PER CENT OF MAXIMUM MOTOR TENSION
		grams	
Tibialis anticus	Internal Saphenous	800	32
	Ext. Cut. of groin	1,060	37
	Superf. obturator	165	6.7
	Deep obturator	400	16
	N. to quadriceps and Sartorius	1,190	44
	Small sciatic	1,320	45
	Popliteal	1,820	78
Semitendinosus	Internal Saphenous	1,900	63
	Ext. Cut. of groin	830	28
	Superf. obturator	1,270	42
	N. to quadriceps and Sartorius	2,740	91
	Small sciatic	?	62

Furthermore, the motor units² excited through one afferent nerve do not lie in a single muscle, but are distributed throughout many different and often widely separated muscles. In table

² By a "motor unit" is meant a single motor neuron and the bunch or "squad" of about 100 muscle fibers which it supplies. Close to the muscle and within it, each nerve fiber divides dichotomously into several daughter fibers, each of which ends in one of the 100 or so muscle cells. The semitendinosus muscle of the cat has some 630 such motor units, the gastrocnemius medius 430, the extensor longus digit 330 and the soleus 250. By dividing the total tension developed in a muscle during maximal stimulation of its motor nerve by the number of motor units, the average contraction tension of a single motor unit, is obtained. The values found by Eccles and Sherrington were 5.5, 30.1, 9.9, 8.6 grams respectively for the semitendinosus, gastrocnemius medius, soleus and extensor longus digit.

76 are shown the reflex tensions developed respectively in the tibialis anticus and semimembranosus as a result of stimulation of various afferent nerves. In the last column these tensions are given as percentages of those developed by direct stimulation of the motor nerves (motor tension). It will be noted that the fraction of the motor unit activated by the different afferent nerves varies widely, those nerves more closely allied segmentally to the motor innervation involving a larger proportion of the units of the muscle than those more remote.

The principle of convergence; occlusion

Evidence that a given group of anterior horn cells is in communication with the central terminals of more than one afferent nerve has already been cited in the paragraphs dealing with spinal induction. This principle of convergence of afferent pathways is shown in other ways. For example if a muscle be strongly excited by the successive stimulation of two afferent nerves it is found that the sum of the reflex tensions developed in the two responses is much greater than the maximum tension developed after a single stimulation of the motor nerve. Obviously there must be a central overlap of the two afferent pathways—a proportion of the motoneurons supplying the muscle must be connected with both.

Also, the sum of the reflex tensions developed when strong stimuli are applied to two afferent nerves successively is often found to be considerably greater than the tension resulting from stimulation of the two nerves simultaneously. The difference in the tension values is called occlusion. For instance, the sum of the tensions developed in the tibialis anticus when the two plantar nerves (afferent) are stimulated consecutively is 3.15 kgm. (1.57 + 1.58 kgm.) whereas the tension following simultaneous stimulation of the same nerves is only 1.81 kgm. (no more than 15 per cent greater than that resulting from the stimulation of one nerve). The occlusion therefore amounts to (3.15 - 1.81) = 1.34 kgm. This result is not due to interference of one afferent pathway with the other, or to inhibition. It is simply due to the fact that a certain proportion of the motoneurons of the reflex is common to the two afferent nerves; the motoneurons common to the two afferents are excited maximally by either nerve alone, so no greater effect upon the muscle can be produced by exciting them through both afferents simultaneously. Occlusion is there-

fore a measure of central overlap, i.e., of convergence of afferent paths (fig. 337A).

Not only in reflexes set up through afferent nerves of similar function and distribution does occlusion occur; it is also evident between reflexes resulting from stimulation of such dissimilar nerves as the internal saphenous and the nerve to the sartorius. The smoothness of reflex action, the interlocking of allied reflexes, the gradual, even passage from one reflex to another and the general coördination of muscular function are the natural consequences of, (1) the fractional control by any one afferent of the centers governing the muscles of a given reflex, and (2) the overlap of the motoneuron fields of afferents governing different reflexes.

"SUBLIMINAL FRINGE." Increasing the strength of the stimulus increases the extent of the central overlap and so of the occlusion. When, on the other hand, the stimulation is weak, occlusion may be absent and the sum of the tensions resulting from the concurrent stimulation of the two afferents will then be greater than the tension developed when they are stimulated successively, i.e., instead of there being a deficit of contraction there is actually augmentation (facilitation). The reason for this will be made clear by reference to figure 337. Strong stimuli set up effective excitatory states in the motoneurons connected with each afferent path; these excitatory fields overlap and concurrent stimulation of the two afferents results in occlusion as just described. Fringing the effective excitatory field (*liminal field*) is a zone in which the excitatory state is beneath the threshold for the discharge of impulses down the motoneurons. This is called the *subliminal fringe* (it is not shown in fig. 337 A). When the stimuli are weak the liminal fields are less extensive and so do not overlap (fig. 337 B). Overlapping of the *subliminal fringes* of the two afferents, however, causes through summation the excitatory state of the overlapped neurons to be raised to the threshold level. Thus motoneurons which are unexcited by either stimulus alone, are excited when both are applied together. The response which results when subthreshold stimuli are applied simultaneously to two afferent nerves (immediate spinal induction) may also be explained by the overlap of subliminal fields.

That subliminal fringes surround excitatory states produced by *maximal* as well as those produced by weak stimulation is shown by the following experiment. Strong faradization of the central end of the internal saphenous nerve causes tetanic contraction of the tensor fasciae femoris. A single break shock applied to the

musculo-cutaneous nerve induces a reflex contraction which lasts for $\frac{1}{2}$ second. Stimulation of the musculo-cutaneous *during* the tetanic contraction induced by the stimulation of the internal saphenous causes an aug-

FIG. 337. A, illustrating occlusion. *a* and *b* are two afferent fibers; *a* when stimulated alone excites the motoneurons within the outlined area; only four motor fibers (α'' , α , α' and β') are represented. *b* when stimulated alone activates the motoneurons in the corresponding area, of which four axons (β' , β , β'' and α') are shown. Thus when the two afferents are stimulated consecutively the motoneurons α' and β' are activated each time, making a total of eight. When stimulated concurrently the total number of activated motoneurons is six, i.e., there is a deficit of contraction due to occlusion. B, weaker stimulation of the afferents *a* and *b*, restricts the respective fields of threshold excitation as shown by the continuous line limit. *a* by itself activates one motoneuron α ; *b* activates β . Concurrently they activate four units (α' , α , β' and β) owing to the summation of the subliminal effect in the overlap of the subliminal fields outlined by the broken lines (from Creed, Denny-Brown, Eccles, Liddell and Sherrington, *Reflex Activity of the Spinal Cord*).

mentation of the contraction which persists for $\frac{1}{2}$ second. The facilitation is attributed to the subliminal fringe caused by stimulation of the musculo-cutaneous being overlapped, and so raised to threshold value, by the

subliminal fringe caused by stimulation of the internal saphenous.

The subliminal fringe provides a mechanism for the linking together of allied reflexes having origins close together or widely separated. It provides a background or, as Sherrington expresses it, a "catch on" for labyrinthine and other types of reinforcement. Stimulation of certain areas of the cerebellum, for instance, produces no effect itself upon limb movements, yet can modify reflex movements already in progress. Again, afferent stimuli too weak to elicit a limb reflex become effective when neck and labyrinthine proprioceptors are stimulated by turning the head, though this movement itself causes no apparent effect. The facilitation of one phase of an alternating reflex by the other (p. 813) is also attributed to the overlap of subliminal fringes persisting for a short period after each phase.

The principle of the final common path

Each fiber composing an afferent nerve is a pathway for impulses arising in a limited number of receptor organs (p. 797). The afferent nerves are private paths through which the receptors communicate with the spinal centers. The motoneurons of a given reflex, on the other hand, are as public roads which must accommodate traffic from a large number of differently located points; upon them impulses from many and various receptive areas of the body converge. This final link in the reflex arc, the motoneuron, is therefore called the *final common path*. Each final common path (F.C.P.) is as the stem of a funnel of which the numerous afferent paths represent the expanded portion (see fig. 326, p. 798 and fig. 338). Conversely, each afferent nerve can communicate with a great many F.C.P.'s. Potentially, every afferent fiber is in communication with all F.C.P.'s. After strychninization, for instance, or the injection of tetanus toxin, a stimulus applied to practically any region of the body induces wide-spread muscular contractions (convulsions). Since all reflex action of muscle is brought about through impulses traversing the final common path, this must subserve a variety of reflex responses. At the entrance to the final path, i.e., at the convergence point of the afferent pathways, excitatory and inhibitory states are set up. It is upon the nature and extent of these that the type and intensity of the resulting reflex depends.

Allied reflexes, i.e., those conjoining to effect

a common purpose, use the path concurrently to reinforce one another. Such reflexes may originate in widely separated regions and from diverse receptors (receptors of skin, eyes, organs of smell, muscle and labyrinthine proprioceptors, etc.). For example, stimulation of the outer digit of the hind foot causes reflex flexion of the same limb. If other digits are stimulated concurrently, the flexion reflex occurs more readily (facilitation, p. 812). Additional stimulation of the contralateral fore foot or pinna or of the tail further reinforces the flexion response.

Antagonistic reflexes, on the contrary, cannot occupy the final path simultaneously; the most important of two such reflexes must give way. For example, during the scratch reflex a strong stimulus is applied to an afferent nerve of the limb

FIG. 338. Diagram showing the convergence of various paths upon the anterior horn cell. 1 and 2, afferent fibers from periphery; 3, motoneuron (final common path); 4, corticospinal fiber; 5, rubrospinal fiber; 6, reticulospinal fiber; 7, vestibulospinal fiber. Part from Lennox and Cobb, redrawn and modified.

engaged in the scratching movements, the limb becomes strongly flexed, i.e., the scratch reflex gives place to the flexion reflex. Protective reflexes, e.g., those set up by injurious agents are accompanied by pain in the conscious animal and are prepotent, displacing less urgent responses from the final common path. The flexion reflex (see below) which withdraws the foot from a noxious influence is a reflex of this nature.

Reciprocal innervation

Voluntary or reflex contraction of a muscle, e.g., the biceps, is accompanied by the simultaneous relaxation of its antagonist—the triceps. Reciprocal innervation of antagonistic muscles is illustrated by the following experiment. When

the paw of a spinal or decerebrate animal (p. 825) is pinched, pricked, burned or stimulated by a strong electric shock, or the central end of the peroneal nerve excited, there results in the same limb a strong contraction of the flexor muscles of the ankle, knee and hip, together with inhibition of the extensors. This is the *flexion* or *withdrawal* reflex. In the contralateral limb the picture is reversed. There occurs contraction of the extensors together with inhibition of the flexors—the *crossed extension reflex* (fig. 339 and

the extensors, and the limb, if it be in such a position that it can be acted upon by gravity flexes at the knee. (Reciprocal innervation of the eye muscles is described on page 1017).

The inhibitory effect upon the skeletal muscles is not brought about through specific inhibitory nerves as in the case of cardiac inhibition (vagus) or of the inhibition of the intestine (sympathetic). Direct stimulation of a muscular nerve results only in excitation. The inhibitory process is therefore central in origin. The reciprocal inhibition of

FIG. 339. Reciprocal action of antagonistic muscles. Record from leg of a decerebrate cat; F, flexor; E, extensor. The myograph writer for the extensor muscle is set a little to the right of that for the flexor muscle in order that the two may clear each other. The ascent of F and the descent of E are actually synchronous (from Sherrington).

340). The purpose in these reflex reactions is obvious; when an animal's paw is painfully stimulated the flexor muscles contract to withdraw the limb while contraction of the extensors of the opposite limb stiffen it for the support of the body.

The reciprocal inhibition of the knee extensors in the flexion reflex may be demonstrated more clearly after abolishing the action of the flexor muscles by sectioning their tendons; stimulation of the afferent nerve is followed by relaxation of

FIG. 340. Diagram illustrating reciprocal innervation. The afferent fibers (α) from skin of leg and (α') from the flexor muscles of the knee (in hamstring nerve) pass to the spinal cord, where each divides into two. One division goes to a motoneuron (ϵ) of the extensor muscles (E) and the other to a motoneuron (δ) of the flexor muscles (F). A branch of each afferent also crosses the mid-line to similar motoneurons (ϵ' and δ') on the opposite side of the cord. The afferent impulses, as indicated by the plus and minus signs either excite or inhibit the motoneurons, the respective effect being a function of the synapse. For the sake of simplicity internuncial neurons between the afferent and efferent neurons have been omitted (after Sherrington).

muscles which results from the stimulation of an afferent nerve is due simply to the cessation of excitatory impulses along the motoneuron, which may result, as suggested by Gasser, from certain connecting (internuncial) neurons having entered the phase of subnormal excitability. This phase corresponds to the positive after potential as recorded from the cord (p. 789).

Central inhibition

Examples other than the one mentioned in the last section may be cited and will serve to illustrate

certain features of the central inhibitory process. If during the progress of a flexion reflex a contralateral nerve is strongly stimulated the reflex is inhibited. Or, if the contralateral nerve is stimulated by a single break shock a short time *before* a similar shock is applied to the ipsilateral nerve, the after-coming flexor response is reduced. The degree of inhibition brought about depends not only upon the strength of the inhibitory (contralateral) stimulus itself but is related inversely to the strength of the excitatory (ipsilateral) stimulus. In other words, one effect is pitted against the other and the algebraic sum of the two opposed effects determines the intensity of the flexor response. The extent of the inhibitory effect caused by the contralateral stimulation is related to the length of the interval by which it precedes the ipsilateral stimulation. The maximal inhibitory effect is obtained when the interval is about 50 msec. (30 to 80 msec.). Shortening or lengthening the interval reduces the inhibition so that it is absent if the interval is less than about 6 msec or greater than 200 msec or so. The absence of the inhibitory effect when the interval is short, is ascribed to the slow development of the inhibitory as compared with the excitatory state. The diminution in the effect as the interval is lengthened is attributed to the subsidence of the inhibitory state before the excitatory state has been developed.

Several other examples of central inhibition have been demonstrated recently. Thus, the discharge of impulses set up in the motoneurons to the vastus internus muscle by stimulation of the 6th L. posterior spinal nerve root, is inhibited by concurrent stimulation of the 7th L. posterior root (Renshaw).

Inhibitory, like excitatory effects, undergo summation; varying degrees of inhibition are therefore possible. For example, two inhibitory stimuli, applied a short interval apart (less than 60 msec.) to an afferent nerve cause a greater effect than does one alone, and a series of inhibitory volleys causes a gradually increasing inhibition. Summation of inhibition also results when the two contralateral nerves are stimulated simultaneously or at a short interval apart. The principles of convergence and overlap of liminal and subliminal fields (p. 817) apply, apparently, to inhibitory as well as to excitatory states. Fractionation of the reflex center in regard to inhibition analogous to that described for excitation (p. 815) also apparently exists. Inhibition shows recruitment (p. 814) and an after action

analogous to the after discharge of excitatory states (p. 814).

No satisfactory theory has yet been formulated to explain central inhibition. The relatively prolonged nature of the inhibitory process suggested that a chemical mediator of some kind is responsible, but there is no evidence to support such an idea. The theory of Wedensky has been called upon to account for central inhibition but its inadequacy is generally accepted. Certain types of central inhibition, for instance that of the flexion reflex, appear to be due to impulses falling in the subnormal phase which are too weak themselves to cause a response yet to block excitatory impulses.

The nature of central excitatory (C. E. S.) and central inhibitory (C.I.S.) states

Sherrington and his associates have given a new conception of central nervous activity. According to this school, the reflex centers should no longer be looked upon as exchanges where impulses arriving at the afferent terminals are merely "switched" to the appropriate efferent paths. Afferent impulses upon their arrival at the motor neurons (i.e., at the synapses) create central excitatory states (C.E.S.) of longer duration than the impulses themselves and are capable of summation; or central inhibitory states (C.I.S.) are produced which can sum likewise. As a result, the reflex center is capable of discharging at its own rhythm and of grading its response though the impulses which it receives are "all or none" in character. The sign and intensity of the resulting reflex action is dependent upon the relative values of these states developed at the motoneurons of the final common path. If the C.E.S. is of subthreshold value a discharge of impulses does not result. As soon as it rises above the threshold value a discharge of impulses occurs; for this reason it is not possible to build the C.E.S. above threshold value. The frequency of the impulses and so the magnitude of the reflex response is dependent upon the rate at which the C.E.S. is built up. It has already been mentioned that a single impulse is rarely, if ever, capable of raising the C.E.S. to threshold value, the summation of the effect of two or more impulses being necessary. If the C.E.S. is antagonized by the C.I.S. the central excitatory state is reduced or completely abolished. The C.E.S. takes a certain length of time to develop to threshold value, the inhibitory state a longer time. Each persists for an appreciable period during which its intensity

gradually diminishes; the C.I.S. lasts for a longer time than does the C.E.S.

The C.E.S. accumulated as a result of afferent impulses is dissipated by an antidromic volley; this is shown by the following experiment. When two single shocks of equal intensity and separated by a short interval are applied to an afferent nerve, the second response is greater than it would have been had it not been preceded by the first (facilitation). If between two stimuli (and about 18 σ after the first) the motor nerve³ of the muscle be stimulated so as to "back" a volley of impulses into the reflex center, i.e., antidromically, the second response shows little or no facilitation. The annulment of the facilitation is ascribed to the inactivation of the C.E.S. formed by the afferent volley in the subliminal fringe of the motor neurons (p. 817). Also an antidromic volley set up during the after discharge of the flexor reflex is followed by a period of quiescence lasting for 20 msec to 50 msec,⁴ that is, the after discharge is cut short, due to inactivation of C.E.S.

Whereas C.E.S. induces a discharge of impulses down a motoneuron, the development of C.I.S. results in a cessation of impulse discharge. An antidromic volley has no effect upon C.I.S. The central inhibitory state is therefore looked upon simply as the inactivation of the central excitatory state, having no direct effect upon the motoneurons. In other words, if central inhibition exists, the antidromic volley finds C.E.S. already inactivated and so can produce no other effect.

The overlap of excitatory fields has been considered (p. 316). Overlap of an excitatory field by an inhibitory field is indicated by the following observation. A weak inhibitory stimulus pitted against a weak excita-

The posterior spinal roots of the nerve are sectioned in order to block any afferent impulses.

The antidromic volley, it is believed, does not pass beyond the surface film interposed between the motoneuron and the afferent terminals, i.e., the synapse. The latter is therefore considered to be the site where accumulation of C.E.S. occurs.

tory stimulus frequently fails to reduce the latter's effect. If, however, the *excitatory* stimulus is increased, then the weak inhibitory one is definitely effective. This result is best explained by the conception that the excitatory field has been enlarged by the stronger stimulus and so has been overlapped by the inhibitory field.

The nature of the fundamental process underlying the central excitatory state and transmission across the synapse has been a subject of speculation and controversy for a number of years. The question has not received a final answer but recent research has contributed several important facts leading to considerable clarification. It has been taught for many years that certain phenomena, e.g., one way conduction, temporal summation, latency and the transmission of impulses across a non-conducting gap (the synapse) were peculiar to reflex action and dependent upon the specific properties of the synapse. However, all of these phenomena can be demonstrated in the nerve fiber and it is becoming more and more evident that synaptic transmission and nerve fiber conduction are basically similar, the differences are of a minor character and can be explained largely by differences in organization and time relationships. Keith Lucas' conception of the synapse as a region of decrement probably comes nearer to the truth than any other. The role played by acetylcholine in central excitation is also now thought to be essentially the same as that which it plays in excitation of the nerve fiber. This subject will be dealt with in Chapter LXXIII. We shall see there that the electrical and chemical theories of synaptic (and neuromuscular transmission) can be reconciled, for the action potential and the production of acetylcholine appear to be closely related phenomena, indeed, interdependent parts of the same basic process.

CHAPTER LXVI

THE PHYSIOLOGICAL MECHANISMS GOVERNING POSTURE AND EQUILIBRIUM

STRETCH OR MYOTATIC REFLEXES

The reflex contraction of a healthy muscle which results from a pull upon its tendon is called the stretch or myotatic reflex. Any attempt to flex the limb of a decerebrate preparation, for example, meets with considerable resistance. This is due to the reflex contraction of the extensor muscles whose receptors (muscle spindles) are sensitive to a stretch stimulus (p. 805). After the section of either its motor or afferent nerve the response is very greatly reduced, the muscle then offering little resistance to passive flexion. In figure 341 are shown records of the reflex response to stretching the knee extensor (quadriceps) before and after section of its motor nerve. Liddell and Sherrington found that stretching the muscle by as little as 0.8 per cent of its original length was sufficient to evoke a reflex response. The tension developed may amount to as much as 2,000 grams. Slow as well as rapid stretching of the muscle elicits the reflex. The strength of the contraction continues to increase within limits so long as the stretching force increases; this fact, in view of the results of Adrian and of Matthews (p. 806), is probably due to a rise in frequency of the discharge from individual muscle receptors (muscle spindles) as well as to more of these being stimulated—*peripheral recruitment*—the force of the muscular contraction is thus automatically adjusted to the degree of stretching force applied.

A stretch of constant degree causes a maintained steady contraction, the muscle spindles and the stretch receptors in tendons showing very slow adaptation (p. 807). The reflex ceases immediately upon withdrawal of the stretching force, i.e., it shows little or no after discharge (p. 814). Its latent period is short, less than 20 m. sec. It is readily inhibited by stimulation of an ipsilateral or contralateral afferent nerve or by stretching the antagonistic flexor muscle; overextension in the intact animal is thus automatically prevented. The stretch reflex is obtained predominantly from those muscles which maintain the body's posture, e.g., quadriceps, soleus, gastrocnemius and other extensors. In the decerebrate animal flexors show little or no response to steady stretch, but in the intact or thalamic animal the flexors also exhibit

these reflexes (see supporting reactions). labyrinthine and neck reflexes exert their effect upon the limb muscles, chiefly, through the forcement of myotatic reflexes.

The knee and ankle jerks

A sharp tap upon the patellar tendon, when the knee joint is semi-flexed and the leg dependent causes a short twitch of the knee extensor. A blow upon the tendo Achillis causes a contraction of the calf muscles. These contractions or jerks, as well as those described below for the upper limb, are "fractional examples of the stretch reflex" and are not due to stimulation of the tendon or to direct stimulation of the muscle. The tap causes a sudden momentary stretch of the muscle (a stretch of 0.05 mm less in $\frac{1}{20}$ second being sufficient to elicit the response). Rendering the tendon itself insensible by means of cocaine does not prevent the response. A voluntary action, such as clasping the hands together, reinforces the reflex and increases the force of the jerk. *Patellar or ankle clonus* consists of a rapid rhythmical series of twitches of quadriceps or calf muscles, respectively, which results from the application of a sudden stretch stimulus when, as in a lesion of the pyramidal tract, the reflex arc concerned is abnormally excitable. A sharp depression of the patella by the examiner or a sharp dorsi-flexion of the ankle elicits the respective clonic response. The center for the knee jerk in the human subject lies in the 2nd, 3rd and 4th lumbar segments of the cord; it is innervated through the anterior crural nerve. The center for the ankle jerk is situated in the 1st and 2nd sacral segments; the peripheral nerve is the sciatic.

For a long time the knee jerk was thought to be a direct response of the muscle and not a reflex since its latent period was only some 6 to 12 m. sec. The revised estimates of the speed of conduction in peripheral nerve (up to 100 meters per second) show that this time is not too short for the occurrence of a purely spinal reflex, which the knee jerk is now generally accepted to be. Johnstone found the reduced reflex time (p. 812) to be only 2 m. sec. Any condition, such as decerebration

to the pyramidal tracts (p. 863), which increases the stretch reflexes increases the tendon jerks. They are abolished by an injury or disease involving the efferent or afferent limb of the reflex or the center itself (anterior horn cells). On account of its brief twitch-like character the knee jerk is sometimes spoken of as the "phasic reaction" of the stretch reflex, whereas the sustained contraction resulting from a continuous pull upon the tendon, and which is concerned in the maintenance of posture, is referred to as the "static postural reaction" of the stretch reflex. The jerk is less subject to abnormal states, e.g., spinal transection, anesthetics, circulatory failures, than are the postural reactions. In an animal such as the dog or rabbit, the knee jerk is absent in a few minutes after spinal transection,

341. The stretch reflex of the quadriceps (cat). M is the response (M) before and (P) after cutting the muscle. T is a record of the table-fall stretches the muscle. At the right is shown the reflex inhibition, evoked between i and i' by stimulation of afferent fibers in the ipsilateral peroneo-nerve (from Liddell and Sherrington).

monkey after some days. In man, though reflex activity is entirely lost, the muscles are quite flaccid, the knee jerk is elicitable in man free in from 3 to 7 weeks after a complete lesion of the cord (see p. 870).

Tendon reflexes of the upper limb

are the biceps, triceps and supinator jerks. The *biceps jerk* is elicited by a sharp tap upon the tendon; the response consists of a quick contraction of the biceps with flexion of the elbow. The center for the reflex is situated in the 5th

and the electrical responses are recorded from the animal during the elicitation of a tendon jerk. The contraction of action currents is found to occur at the actual contraction of the muscle. This, the "silent period" is probably due to the muscle spindles being relieved of stretch as the muscle contracts (see p. 805).

and 6th cervical segments of the cord; it is innervated through the musculocutaneous nerve.

The *triceps jerk* is evoked by a blow upon the triceps tendon just above the olecranon process of the ulna; contraction of the muscle and extension of the elbow result. The center for the response lies in the 6th and 7th cervical segments; the peripheral nerve is the musculospiral (radial).

The *supinator jerk* consists of contraction of the supinator muscle and flexion of the elbow; it follows a blow upon the styloid process of the radius. The center lies in the 5th and 6th cervical segments of the cord; the peripheral nerve is the musculospiral.

THE TONE OF SKELETAL MUSCLE

As a result chiefly of the work of the Sherrington school the word "tone" or "tonus" as applied to skeletal muscle has acquired a clearly defined meaning which previously it had lacked. Muscle tone is the steady reflex contraction which resides in the muscles concerned in maintaining the posture characteristic of a given animal species. To use Sherrington's words "reflex tonus is postural contraction." Tonus has its basis in the "static reactions" of the stretch reflexes, and its seat is therefore mainly in the *antigravity muscles*. In most mammals these are extensor muscles and we shall see that in decerebrate rigidity the animal exhibits an attitude which is a caricature of standing, due to an exaggeration of the tone of the extensors.

In man the antigravity muscles and consequently those which exhibit the greatest degree of tone are the retractors of the neck, the elevators of the jaw (masseters), the supraspinatus, the extensors of the back, the ventral muscles of the abdominal wall (probably), and the extensors of the knee and ankle (vastocruureus, gastrocnemius and soleus). When these muscles are completely relaxed, as in an unconscious person, the body collapses. In the healthy conscious person, stretch reflexes are largely instrumental in preventing this occurrence for, as we have seen, the elongation of an antigravity muscle by less than 1 per cent of its length stimulates the muscle spindles and a sustained reflex contraction results (see also supporting reactions, p. 833).

Though the fundamental basis of tonus in voluntary muscle is the myotatic reflex centered in the cord, the tonus state is influenced profoundly by higher centers. Impulses from labyrinthine and neck muscle receptors (p. 830) exert their influ-

ence upon this background of tonus established through lower spinal centers. Similarly, pathways from cerebellar, midbrain and cerebral centers convey impulses which, impinging upon the final common path, are capable of altering the degree of tonus, of effecting finer adjustments in the tonus state and of maintaining a normal distribution of tonus between groups of muscles (fig. 338, p. 818). The tone of a given group of muscles may also be influenced through the spinal centers by impulses arising in other muscle groups (e.g., neck muscles and the muscles of the digits, ankle and wrist, as in the positive supporting reaction) and in skin receptors.

When the spinal centers are separated from higher centers, extensor tone is abolished (see spinal shock, p. 828). Also, since it is dependent upon stretch reflexes, muscular tone is lost after injury to the afferent or efferent nerves, or to the center itself.

A feature of tonic contraction is its economy in the expenditure of energy. Posture is maintained for long periods with little or no evidence of fatigue, e.g., in decerebrate rigidity; in the maintained closure of the jaws, standing or sitting in the normal person; and in the clasping reflex of the frog. The increase in metabolism is less than in the case of those ordinary contractions which result in movement, though the difference is not as great as was once supposed.² It had also been thought that tonic contractions were unaccompanied by action currents. This, however, has been shown to be an error. The work of Forbes and of Adrian and their associates indicates that the economy of energy is effected through different groups of muscle fibers contracting in relays, only a proportion of the total number of fiber groups of the muscle being active at any moment. Thus, active groups mingled with inactive groups are scattered throughout the muscle. The alternating periods of rest and activity of the muscle groups explains the ability of the tonic contraction to be maintained for so long without showing fatigue.

Red and white muscle

The skeletal muscles of many animals, e.g., birds, rabbit, cat, etc., can be clearly divided into two types,

² In the normal human subject postural contractions cause a rise of from 50 to 70 per cent in the basal metabolism. In certain nervous states, in which the body is maintained in fixed attitudes for long periods (catatonial), the increase in metabolism resulting from the tonic contraction of the muscles is less (20 per cent) than in the case of the normal subject. The circulatory effects of sustained posture are also less pronounced in the pathological cases (Gayler and Wishart, *Brain*, 1933, 56, 282).

(a) *red or dark*, and (b) *white or pale*. The former, compared with the latter, are composed of fibers having a granular and more opaque appearance, possessing more distinct longitudinal striations but less pronounced cross striations, and containing a larger proportion of sarcoplasm.³ The *red* fibers contract more slowly, fatigue less readily, and are tetanized at a slower rate of stimulation than are the *pale* fibers. The *pale* fibers are translucent, show prominent cross striations and a small quantity of sarcoplasm. Muscles which execute rapid movements are usually composed of the pale variety, whereas muscles which execute slower movements are carried out chiefly by the red fibers. It is probable that all muscles are a mixture of the two types of fiber, but that in some the red type predominates, and in others the pale type predominates. The segregation of the two types of fiber in different muscles is more pronounced in some animals, e.g., the bird, rabbit, than in others. In man and the monkey two kinds of muscle can be distinguished with

FIG. 342. The reflex effect of the labyrinthine stimulation on neck reflexes on red and pale muscle. Preparation with section of brain-stem slightly anterior to superior colliculi. naked eye, though the differences are not so pronounced. The predominance of one type of fiber, can, however, be readily made out with a microscope. The rapidly contracting muscles are largely composed of the pale fibers, while the slowly contracting, pale component is the characteristic of the deep, slowly acting dark head. For example, the gastrocnemius contracts rapidly and contains a large proportion of the pale fibers, while the slowly contracting soleus. The latter is composed of the red fibers and contracts rapidly. The short head of the triceps is pale and contracts rapidly, while the long head is dark and contracts more slowly. The slowly acting deep components of the figure are those which respond most readily to a sudden stimulus, and so show the greatest rigidity. They are the "focus of the stretch reflex" and upon them that labyrinthine and vestibular reflexes are mainly exhibited. The rapidly contracting muscles are more especially concerned with the maintenance of posture.

³ They resemble the intrafusal fibers of the spindle (p. 805).

ements. No hard and fast line, however, exists, since both types of extensor muscle and both take part in phasic contractions.

Action of the sympathetic innervation of skeletal muscle

Apparent dissimilarities between postural or tonic contractions and the rapid contractions resulting from phasic contractions have led some investigators to believe that these two types of muscular activity are fundamentally different. A theory has been put up which postulated two components in muscular activity. A plastic element (plastic tonus) is due to the sarcoplasm of the muscle fiber, and is dependent upon sympathetic innervation and a contractile element (so-called contractile tonus) involving phasic contractions, it was supposed, were dependent solely upon the sarcostyles and somatic innervation. The red muscles, which are rich in sarcomeres and undergo tonic contraction upon somatic and sympathetic innervation. The red muscles contain a large proportion of fibers rich in sarcomeres and were therefore considered to be the "bar excellence." That the red muscles undergo a greater degree than do white muscles, and that there are two types of contraction, one dependent upon the sarcoplasm and under sympathetic innervation, is not generally accepted. Hunter and others carried out experiments upon birds and goats designed to support the theory of the dual nature of muscular activity and sought to apply it to the treatment of certain nervous conditions in man associated with increased tone (spasticity). They sectioned the sympathetic communicantes conveying sympathetic innervation to the affected limb and reported favorable results upon the hypertonic condition. The benefits obtained can be easily explained, however, are questionable in the spastic condition and may be attributed to the release of the limb which constitutes part of the treatment. Upon moving the limb to a new position the muscles undergo alterations in the circulation, a purely psychic effect, rather than upon the muscle fiber of the limb. These reactions are Moreover, the theory upon which the reaction is based is not supported by recent work. The lengthening of the muscle is due to muscular contraction, and is due to muscular contraction, and is due to muscular contraction. The muscle is not the same in nature as the muscle which is contracted. Non-medullated nerve fibers are described by several workers as occurring in muscle fibers in structures other than ordinary motor end plates. These fibers, from their appearance, have been called "grape endings" (*terminaisons en grappes*), and it is reported that these endings are located in a section of the ventral spinal cord between the posterior root ganglia, if the posterior root ganglia are left intact, it was concluded

that they belonged to the sympathetic system. The recent degeneration experiments of Tiegs, however, indicate that the grape endings are terminations of somatic motor nerves. When the hind part of the spinal cord in the snake (python) was destroyed by passing a probe up the vertebral canal after amputation of the tail-tip, the grape endings in the muscle which had received their innervations from this part of the cord disappeared. The postganglionic sympathetic fibers and the posterior root ganglia were of course undisturbed by the operation. Moreover, no sympathetic fibers, other than those supplying the blood vessels, were found in the muscle.

In the light of these histological findings, how is the Orbeli effect to be explained? Orbeli found that the fatigue of a muscle stimulated *through its nerve* (i.e., indirectly) was reduced by concurrent stimulation of sympathetic fibers going to the muscle. Sympathetic stimulation was, however, without effect upon the contractions of a muscle stimulated *directly*. These results lead to the conclusion that the sympathetic effect was exerted upon the motor-end plate. Corkill

FIG. 343. Diagram showing "grape endings" (*terminaisons en grappes*) upon skeletal muscle.

and Tiegs have recently confirmed Orbeli's observations. Nevertheless, since the muscle fibers themselves are apparently devoid of sympathetic innervation, at any rate none have ever been described as terminating in the motor end plate, the effect, it is suggested, results from the liberation of an adrenaline-like substance (sympathin) from vascular sympathetic endings. (See fig. 344.) The action of adrenaline in postponing muscular fatigue has been mentioned p. 687.

DECEREBRATE RIGIDITY

This is the term applied to the sustained contraction of the extensor muscles which supervenes upon transection of the brain stem at any level between the anterior colliculi and the vestibular nuclei.⁴ The animal assumes a characteristic attitude with limbs stiffly extended, head retracted,

⁴ Decerebration can also be produced by tying the common carotids and the basilar artery at the center of the pons and thereby depriving the fore-brain of its blood supply.

FIG. 344. The effect of sympathetic stimulation (upper tracing) and of adrenaline (lower tracing) on fatigue of skeletal muscle activated through its motor nerve (from Corkill and Tiegs).

FIG. 345. A suspended decerebrate cat showing extensor rigidity. In A, the labyrinths are intact. B, a decerebrate and labyrinthectomized animal. As a result of the destruction of the labyrinths the head has dropped; this position of the head induces reflex flexion of the fore-limbs and extension of the hind-limbs (tonic neck reflexes, p. 830) (after Pollock and Davis).

jaws closed, and tail horizontal or erect. When placed upon its feet the limbs support the weight of the body (fig. 345A). The position is a caricature of the normal standing position. The knee

jerk and other stretch reflexes (p. 82) generated. The righting reflexes are absent. Neck and labyrinthine reflexes are retained. Ability to regulate the body temperature

In some instances there is increased tonic rigidity as well, but the characteristic feature of rigidity is the tonic contraction of the muscles to maintain the posture. (p. 823, the antigravity muscles). It is pointed out that in the frog which is suspended with flexed thighs, legs and arms, the muscles which are the site of decerebration are the sloth whose habit is to suspend itself from a tree by its arms. The characteristic result of decerebration is basal flexion of the wings which is based on the position of the wing muscles which hold the body in an erect position. In the decerebrate animal the muscles which hold the body in an erect position show increased rigidity. This is decerebrate rigidity which has been described without the muscles in skeletal

The reflex nature of the structures,

Labyrinthine preparation. Little is known of the tone of the neck after decerebration. After destruction of the cerebellum, after preparation the head of the animal falls into the fully extended position.

the forelimbs in turn is maintained through proprioceptive reflexes initiated in the extended neck muscles as well as directly through labyrinthine reflexes (p. 830). After labyrinthectomy, therefore, the flexed position assumed by the head sets up proprioceptive impulses from the neck muscles which lead to a reduction in the extensor tone of the forelimbs; these then become strongly flexed upon the chest (fig. 345 B). If the neck muscles of the labyrinthectomized animal are deafferented, movements of the head are without effect upon the extensor muscles of either fore or hind limbs; deafferentation of the forelimb muscles themselves is followed by little change in the extensor tone of the forelimbs. On the contrary, the extensor rigidity of the hind limbs, is affected relatively little by labyrinthectomy or deafferentation of the neck muscles, but is abolished by deafferentation of the hind limb muscles themselves. To sum up, the tone of the forelimb extensors is maintained chiefly by labyrinthine and neck reflexes, proprioceptive impulses from the forelimb muscles themselves playing a very minor part. In the hind limbs the extensor rigidity is maintained mainly through proprioceptive reflexes initiated from the corresponding limb muscles.

Lengthening and shortening reactions

Attempts at passive flexion of the extended limb of the decerebrate (or chronic spinal) preparation are met by considerable resistance. If the force maintains inhibition of the stretch reflex (upon which the resistance depends) results; the limb gives way suddenly (*clasp-knife effect*) and may now be easily flexed to any degree. The elongation of the extensors which permits the flexion of the limb is called the "*lengthening reaction*." Upon moving the limb again into the extended position the muscle shortens adaptively to the new position. This is the "*shortening reaction*." These reactions give the muscles a certain plasticity. The giving way of the extensor spasm in the lengthening reaction has been ascribed to the giving up of inhibitory proprioceptive impulses to the muscle when the stretch stimulus reaches a certain intensity. As the knee extensor is initiated a contraction of the opposite knee extensor occurs; this is known as Phillipson's reflex.

mals showed extensor rigidity up to the day of death, though as time elapsed the condition tended to be less constant, intervals of reduced extensor and increased flexor tone alternating with those showing the typical decerebrate posture. The fact that extensor rigidity was present so long after operation makes it clear that the condition is not due to the irritation of fibers at the line of section, for these must have undergone degeneration before the end of the survival period. Decerebrate rigidity is evidently due to the release from higher control of a center or centers situated below the level of the transection. The rigidity persists after removal of the cerebellum (cerebellar stimulation actually inhibits the extensor rigidity) but is abolished by destruction of the vestibular nuclei or of the vestibulospinal tracts. The vestibular nuclei or structures in their immediate vicinity therefore appear to be the centers mainly responsible for decerebrate rigidity.

Some of the pseudoaffective reactions characteristic of the thalamic or decorticate animal (p. 884) are seen in the decerebrate preparation to a minor degree. Bazett and Penfield record that in their chronic decerebrate animals stimulation of the preparation, as by twisting the ear, caused lashing of the tail; kicking and running movements were induced by merely touching the animal. Purring followed the introduction of milk into the stomach. Other reflexes whose centers are apparently located in the medulla consisted of motions of chewing and swallowing upon the passage of a stomach tube, and licking movements upon its removal; growling, mewling or crying also occurred in response to various types of stimulus. Auditory reflexes, consisting of movements of the head, limbs or tail, in response to certain sounds, especially to a small scratching sound resembling that made by a mouse were also observed.

The origin of the influence from which the lower centers are released by decerebration is not definitely known. According to Rademaker the red nucleus is responsible for the normal distribution of tone. He reported that transection of the brain anterior to the red nucleus did not result in extensor rigidity, whereas the latter followed immediately upon the destruction of the red nucleus itself, or section of the rubrospinal tracts at the decussation of Forel. These findings are not, however, in accord with those of other workers, and the view that the red nucleus bears an essential relationship to the development of extensor rigidity is no longer generally accepted.
Bazett et al.

rigidity was produced by division of the anterior part of the mid-brain which apparently differed in no respect from that resulting from transection behind the red nuclei. Kellar and Hare, and Ranson and his associates also found that lesions which completely destroyed, but were restricted to, the red nuclei caused an increase in extensor tone which was quite mild as compared with that characteristic of the decerebrate preparation.

The thalamic animal shows a nearly normal distribution of tone but, as just mentioned, well marked extensor rigidity ensues upon section of the brain through the anterior part of the mid-brain, i.e., at about the level of the posterior part of the thalamus. These facts point to the diencephalon (possibly the hypothalamus) as the origin of the tracts whose division causes the abnormal tonus distribution. Yet the thalamic or decorticated animal does show some tendency towards extensor rigidity (p. 829) which indicates that the cerebral cortex also plays a part in regulating the activity of the lower tonic centers. It is probable therefore that for the full development of decerebrate rigidity the removal of both cortical and diencephalic influences is required. The question whether the cortical influence emanates from the motor or premotor cortex has not been definitely settled (see p. 890). According to Elliott Smith and Abbie the frontopontine tracts, which descend from the premotor cortex through the mid-brain to the pons, convey impulses which normally serve to release the limb muscles from the rigidity of the standing posture. Section of these tracts or ablation of the premotor cortex would therefore "fix" the muscles and maintain the rigidly extended posture of the limbs which is characteristic of decerebrate preparations. This conception is in harmony with the results of cortical extirpations in the chimpanzee.

Decerebrate rigidity in man

States of hypertonus resembling decerebrate rigidity are seen in certain nervous diseases. The spasticity of the hemiplegic limbs, for example, has been compared with the experimental condition, but the hypertonus is, as a rule, much less pronounced in the hemiplegic patient than in the decerebrate animal. Moreover, in hemiplegia, though the lower limbs are extended, in the arm it is the flexor muscles which are hypertonic. It may be mentioned, however, in this connection that in the ape standing upon its hind limbs the flexors of the forelimbs are the postural muscles and hold the limbs in a semiflexed position.

gravity; it is these muscles, as already mentioned, which show rigidity after decerebration. When on the other hand, the animal goes upon all fours the extensor as well as the flexor muscles become hypertonic like those of lower mammals and convert the limbs into rigid supports for the body. It has been shown by Brain that when the hemiplegic patient assumes the quadrupedal position the rigidity also shifts from the flexors of the arm to the extensors; the arm is extended and offers resistance to passive flexion. This suggests that the ordinary flexed position of the hemiplegic arm is in reality, as in the decerebrate ape, a part reflex bipedal standing. Whether the spasticity of hemiplegia is due to pyramidal or extra-pyramidal involvement has been a debatable question, but it is most likely the result of injury to the lateral system (p. 890).

Rigidity is a pronounced feature of striatal disease but it differs from decerebrate rigidity in that the flexors as well as the extensors are hypertonic.

A posture which is most closely comparable with decerebrate rigidity is seen in association with hydrocephalus or lesions of the mid-brain. In such cases the four limbs are rigidly extended. Such lesions tend to cause extensive destruction of nervous tissue which further supports the view that the full development of decerebrate rigidity is due to the interruption of more than one descending pathway.

THE SPINAL STATE

Transection of the cord produces an immediate flaccid paralysis of the muscles behind the point of section. Immediately after section in the lower cervical region the limbs hang limply, the extensors being quite toneless; the stretch reflexes and other extensor responses cannot be elicited; the startle jerk is abolished. The blood pressure falls to a dangerously low level and vascular and visceromotor reflexes are unobtainable. This condition is called *spinal shock*. Its duration varies with the species. The higher the position of the lesion in the phylogenetic scale the more profound is the shock and the slower is the recovery. In the frog the condition is brief; in the rabbit, cat and dog the startle jerk returns within a few minutes, but in the monkey not for two or three days. Other extensor reflexes, however, remain in abeyance for a longer time. In the cat and dog the startle reflex is still present after a long time. In the cat and dog the startle reflex is still present after a long time. In the cat and dog the startle reflex is still present after a long time.

decerebrate preparation is sectioned, the exaggerated extensor tone characteristic of the latter is replaced (behind the section) by an imbalance in favor of the flexor muscles.

Spinal shock also follows section through the medulla below the vestibular nuclei (*decapitate preparation*).

In the cat and dog spinal shock is gradually covered from over a period of weeks. The blood pressure is restored to normal and the vascular reflexes can again be obtained. The reactions of the extensor muscles return, and the animal is able, though imperfectly and for a few minutes only, to support the weight of the body when placed upon its feet (chronic spinal animal).

Spinal shock is attributed to the removal of impulses which in the intact animal descend from higher centers to reinforce the spinal centers. That it is due to this and not simply to an inhibitory effect of the local injury itself seems clear from the fact that after an animal has recovered from spinal shock, a second transection made behind the original one does not cause a return of the shock state. In the cat and dog the flexor reflexes are evidently dependent only to a minor extent upon the higher centers, since they are capable of being executed by the spinal centers alone. The loss of the extensor reactions results from the removal of vestibular impulses (severance of vestibulospinal tracts) but these reactions can also eventually be carried out by the spinal centers. In the monkey, the immediate effect of cord section upon reflex activity is much more profound, involving the flexors as well as the extensors. The loss of the flexor reactions is probably due to the greater dependence of the flexor spinal centers of this species upon impulse arriving by descending pathways (reticulospinal). Ultimate recovery of reflex activity in the monkey is slight; any which results is confined to the flexors and the knee jerk. The muscles waste and the limbs remain flaccid. The failure of recovery eventually to occur is probably due to degeneration of anterior horn cells below the level of the cord section (atrophy), the long duration of the shocked state permitting the cells to deteriorate beyond the time within which repair is possible (see also p. 871).

THE THALAMIC ANIMAL

This term is given to an animal whose cerebral hemispheres have been removed, leaving the optic thalami intact (see fig. 349). Such preparations retain their righting reflexes and can regulate their body temperature. They are also capable of carrying out coördinated reflex acts and show, even to an exaggerated degree, reactions which in the intact animal are associated with emotional states (fright, anger). Such reactions, which are

termed pseudoaffective, are also exhibited by an animal whose cortex alone has been ablated (see p. 884). In contrast to the decerebrate animal, the distribution of muscular tone in the thalamic animal shows little departure from the normal, though a tendency toward extensor rigidity is evident when the animal is held suspended in mid-air.

STATIC AND STATO-KINETIC REFLEXES

The reflex mechanisms governing the orientation of the head in space, the position of the head in relation to the trunk and the appropriate adjustments of limbs and eyes to the position of the head, are called into action by afferent impulses discharged from receptors situated in (a) the vestibular apparatus (semicircular canals or utricle), (b) the neck muscles, (c) the retina, and (d) in the body wall or limb muscles.

The postural reflexes are classed into two main groups, *static* and *statokinetic*.

(1) *Static reflexes*. These are *general* and *local* or *segmental*. The general static reactions, so called by Magnus because they involve the entire body, or at least four limbs, are (a) the *righting reactions* and (b) the *statotonic* reflexes. The general static reactions are called into play by the deviation of the head from its usual or "natural" position in space (stimulation of receptors of utricle, p. 835) or in relation to the trunk (stimulation of neck muscle receptors). The local or segmental static reactions are confined to one limb or a pair of limbs; examples are, the *supporting reactions* and the *crossed extension reflex*. The latter reflex has been described on page 819.

(2) *Stato-kinetic reflexes*. The actual *movements* of the head bring these reflexes into action (stimulation of receptors in semicircular canals).

When an animal's head moves in space as a result of a movement of the neck, or of a change in the position of the body as a whole, the reflex adjustments of limbs and eyes which accompany a particular movement of the head are brought about through stato-kinetic reactions. The attitude which is thus struck is sustained by a statotonic reflex so long as the head is in the new position. The righting reflexes serve to maintain the normal upright position of the body or to restore this position if as a result of some untoward movement or the application of an external force the animal is thrown upon its side or back. A more detailed account of these different postural reflexes follows.

GENERAL STATIC REFLEXES

THE RIGHTING REFLEXES

The orientation of the head in space is a faculty possessed by all vertebrates and by many invertebrates, and the ability to maintain the head in a definite relationship to the body is a general characteristic of animal life. A cat held back downwards and then allowed to fall through the air lands upon its feet, its body and head assuming a normal attitude. A fish resists any attempt to turn it from its natural position and if placed in the water upon its back flips almost instantly into the normal swimming position. Even a cray-fish rights itself from the back-down position. These righting reactions are complex and involve five separate types of reflex.

FIG. 346. On left, position taken up by a thalamic rabbit with intact labyrinths. As it possesses the labyrinthine righting reflexes, it carries its head in the normal position. On right, position taken up by a rabbit like the preceding but deprived of its labyrinths. The head is not raised towards the normal position (after Magnus).

(a) Labyrinthine righting reflexes acting upon the neck muscles.

(b) Neck righting reflexes acting upon the body.

(c) Body righting reflexes acting upon the head.

(d) Body righting reflexes acting upon the body.

(e) Optical righting reflexes.

The first four of these are demonstrated best upon a thalamic animal (p. 829). When a thalamic rabbit is suspended from the pelvis (fig. 346) the head turns until it assumes its normal position in space, i.e., into the position it would occupy were the animal in its natural position. The maintenance of the head in the new position is due to *labyrinthine righting reflexes* acting upon the neck muscles. Turning the body of the animal through the air into different positions is followed by compensatory movements of the head, its orientation

in space being thereby maintained. A pation of the labyrinths and suspended animal as before, the head shows no compensatory movements; it hangs limply like that of a rabbit.

When the thalamic animal is laid rest its side on a table the head is raised into upright position as a result of the *labyrinthine righting reflexes* just mentioned. The contractile neck muscles which rotate the head sets up proprioceptive impulses, which through the upper cervical cord exert an influence upon the muscles of the body which rotate (first, then pelvis) into the normal relationship to the head. This is the *neck righting reflex acting upon the body*. A labyrinthectomized animal laid upon its side behaves in a somewhat abnormal manner. The reaction under the latter stances is due, however, to the asymmetrical stimulation (pressure of one side of the body against the table) of exteroceptors in the body wall. This is the *body righting reflex acting upon the head*. If a board of a weight equal to that of the animal is laid upon its upper surface, the pressure is thereby disposed equally on the two sides and no compensatory movement of the head occurs.

This reflex is well shown by the labyrinthine dogfish, especially after blinding. When placed upon its side or back the fish despite the absence of labyrinths swims away in the false position. However, it comes into contact with the bottom of the tank the righting reaction immediately occurs. Even worms possess this means of orientation.

Again, when the thalamic animal is laid upon its side but the head held down to the table to eliminate the righting reflexes of labyrinthine and cervical origin, as well as the body righting reflex acting upon the head, the body nevertheless rights itself. This must be due to the asymmetrical pressure upon the body exerting a reaction upon the skeletal musculature, i.e., a *body righting reflex acting upon the body*.

The *optical righting reflexes* are initiated by retinal impressions. They are absent in the thalamic animal since their center is cortical. In many animals, such as the monkey, dog and cat but are a negligible factor in others, such as the rabbit and guinea pig. The absence of the optical righting reflexes in the thalamic species is attributed to their lower cortical development. Yet even the cray-fish deprived

which is the homologue of the utricle of the ear, rights itself, though with less facility usually, when placed upside down in water. Medium righting reflexes due to unequally distributed pressures upon the body surface must also be in abeyance; the righting reaction, apparently entirely of retinal origin. This is so is proved by blinding the animal, in which case the righting reaction is lost completely.

In sum, the righting reflexes may now be studied in their natural sequence. When the animal is placed upon its back the labyrinthine reflex upon the neck muscles turns the head into a normal relationship to the dimensions of space; the proprioceptive reflexes of the neck muscles bring the body into its normal relation to the head. When resting upon a rigid support these reflexes are reinforced by body righting reflexes (head and body). When the animal falls through the air or water, the latter reflexes of course come into play. A labyrinthectomized otherwise normal animal, such as the cat or guinea pig, covers its upright position when allowed to fall through the air, as a result of the operation of the righting reactions; the righting ability is, however, if the eyes are covered with a black cloth. Also, an air-breathing animal deprived of both labyrinths, though a good swimmer, drowns if thrown into deep water, since it cannot orient itself with respect to the sight of surrounding objects. Deaf mutes, guinea pigs, whose labyrinths are very frequently undeveloped, are unable to swim and may drown as a result of their inability to orient themselves when diving into deep water.

Righting reflexes may be demonstrated in the guinea pig. The baby of a few weeks old, for example, when lying prone raises the head into a vertical position. When blindfolded and held by the pelvis in different positions in the air the head is moved toward the normal position.

ATONIC OR ATTITUDINAL REFLEXES

Tonic labyrinthine and neck reflexes acting on the limbs. These reflexes influence the tone of the skeletal muscles and thereby maintain the different parts of the body in an attitude appropriate to a given position of the head. They are investigated best in the decerebrate animal (fig. 347), the righting reflexes being then largely excluded. The proprioceptors concerned are in the labyrinth (tonic labyrinthine (utricle) reflexes) which are brought into play by alterations in the position of the head in relation to the dimensions of space, (b) the neck muscles (tonic

neck reflexes) which come into action when the position of the head is altered relatively to the body. In order to study separately the part played by each of these reflexes in any given reaction, the following procedures are adopted.

A. To exclude the neck reflexes:

(a) Immobilization of the neck of an animal by means of a plaster of Paris bandage in order to prevent movement of the head in relation to the trunk. Any tonic effects resulting from a change in the animal's position must then be due solely to alterations in the position of the head in space (labyrinthine reflexes).

(b) Section of the posterior roots of the first three or four pairs of cervical nerves.

B. To exclude tonic labyrinthine reflexes:

(a) Fixation of the head alone in some suitable apparatus. The tonic effects resulting from movement

FIG. 347. Diagrammatic representation of the positions of an animal's head, each marked with the angle which the labial cleft makes with the horizontal plane (after Magnus).

of the body must then be due to an alteration in the position of the body in relation to the head, i.e., to movements of the neck.

(b) Destruction of both labyrinths, section of the 8th nerves or of the medulla below the vestibular nuclei.

The labyrinthine reflexes exert an influence upon the tone of the extensor muscles which is in the same direction (increase or decrease) in all four limbs. The influence of the neck reflexes, on the other hand, is usually in opposite directions in the fore and hind pairs of limbs. The greatest degree of extensor tone is exerted through the labyrinth mechanism when the animal is supine and the mouth cleft inclined at an angle of 45° (fig. 347) above the horizontal plane.

Extensor tone diminishes as the angle increases; it is minimal in the prone position with the mouth cleft at an angle of 45° below the horizontal plane.

In an animal on all fours the labyrinthine effect is therefore to increase or decrease the extensor tone in the muscles of all four limbs when the head is strongly extended or flexed, respectively. In the decerebrate labyrinthectomized animal, the neck reflexes alone operating, flexion of the forelimbs and extension of the hind limbs occur when the neck is flexed toward the sternum (ventriflexion), (see fig. 345, p. 826). Extension of the neck (dorsiflexion) produces the converse picture, i.e., extension of the forelimbs and flexion of the hind limbs. When therefore the neck is ventriflexed in the decerebrate animal with intact labyrinths, the neck reflexes reinforce the tonic labyrinthine effect upon the forelimbs but antagonize that upon the hind limbs; the usual result is relaxation of the forelimbs with strong extension of the hind limbs. When the neck is extended the

a corner is accompanied by similar effects—extension of the limbs on the side of the body toward which the jaw (or snout) is inclined (*jaw limbs*) and flexion of the limbs on the opposite side (*skull limbs*).

Pressure upon the last cervical vertebra reduces the tone in all four limbs (*vertebra prominens reflex*).

The significance of these reflexes and their importance in the coordination of the postural muscles may be realized when the attitudes of the intact animal are observed. Thus when an animal turns to one side the limbs of that side are stiffened in order to support the body's weight. A cat looking upwards to a bird in a tree extends the forelimbs and flexes the hind limbs, thus giving the back a suitable inclination which improves the position of the head and eyes, and places the body

FIG. 348. Photographs of a normal cat, showing the animal's posture (on left) when its attention is attracted by an object placed above it. Photograph of the same animal (on right) when its attention is drawn to an object below it. The difference between the two positions of the forelimbs is very marked, because in them the neck and labyrinthine reflexes reinforce one another; the hindlimbs are in much the same position in both cases since the two sets of reflexes cancel one another (after Magnus).

neck reflexes reinforce the labyrinthine effect upon the tone of the fore limbs but antagonize that upon the hind limbs. The effect of the neck reflexes upon the extensor tone of the latter again predominates; the extension of the forelimbs is maintained but definite relaxation of the hind limbs occurs.

Rotation of an animal's head (turning in the frontal plane of the skull) causes increased extensor tone of the fore and hind limbs on the side of the body toward which the jaw is rotated (*jaw limbs*)⁵ and reduces the tone of the opposite limbs (*skull limbs*). Inclination of the head toward one shoulder (lateral flexion) as when an animal turns

in a position preparatory for a spring (fig. 348). When looking into a hole or beneath a cupboard the flexion of the forelimbs and extension of the hind quarters gives an opposite but no less advantageous inclination to the body. Depression of the back in the region of the last cervical vertebra brings the animal into a crouching attitude.

Stato-tonic effects may be demonstrated in certain nervous lesions associated with a state analogous to decerebrate rigidity of animals (p. 825). Turning the head to one side, for example, causes an increase in tone of the extensors of the jaw limbs and hypotonicity in the limb muscles of the opposite side).⁶ When the head is in the position for maximal labyrinthine tone, i.e., when the

⁵ Magnus has introduced the term jaw-limbs to indicate the limbs toward which the chin of man or the jaw of animals is rotated or inclined. The opposite limbs i.e., the limbs to which the vertex of the skull is rotated, are called skull-limbs.

⁶ This, according to Magnus, can also be shown in a certain percentage of normal infants, and in hydrocephalus it may be well marked.

patient is supine, and the neck extended the extensor tone of the paralyzed limbs increases, but becomes reduced in the prone position.

(2) *Tonic labyrinthine and cervical reflexes acting upon the eyes.* Tonic effects upon the eye muscles, analogous to those described for the skeletal muscles, result from changes in the position of the head. Labyrinthine and neck reflexes are responsible. Alteration in the position of the head with neck immobilized, or movement of the head in relation to the body after labyrinthectomy, is followed by compensatory eye movements. Turning the head downwards causes an upward movement of the eyes which are held in this position so long as the head position is maintained, the tone of the superior recti and inferior oblique being increased while that of the inferior recti and superior oblique is reduced. A corresponding compensatory movement of the eyes occurs when the head is turned upward. Similarly, when the head is turned to one side the internal and external recti of the two eyes cooperate to deviate the eyes outward or inward in relation to the head. Briefly, the eyes are moved in a direction opposite to that taken by the head; thus their original positions in space are maintained and the visual field existing prior to the head movement remains unaltered. It should be pointed out that the actual movement of the eyes is a stato-kinetic reflex (p. 834) and due to a different mechanism (semicircular canals) from that which maintains the eye position while the head is held in the altered attitude. The latter is a statotonic reflex, dependent upon the utricle.

SUMMARY OF THE CENTERS FOR GENERAL STATIC REFLEXES

Magnus found that all the static reactions mentioned in the foregoing section could be obtained unaltered after removal of the cerebellum, as could also most of the stato-kinetic reflexes to be described in the next section. Nevertheless, this rather surprising fact does not necessarily imply that in the normal intact animal the cerebellum plays no part in these reactions. A contrary conclusion must be drawn from anatomical considerations and from observations in cerebellar disease in which disturbances referable to the labyrinth (e.g., abnormal positions of head, falling, etc.) are manifest. Moreover, Camis has demonstrated the arrival of action currents in the cerebellar nuclei during experimental stimulation (mechanical) of the labyrinth.

(a) *The righting reflexes.* All the labyrinthine righting reflexes, as well as the body righting reflexes acting upon the head, have their centers in the mid-brain. According to Rademaker the labyrinthine righting reflexes are dependent upon the red nucleus. Destruction of the red nuclei or section of the decussation of Forel (p. 875) is claimed by this observer to abolish the righting reflexes.⁷ The center for the optical righting reflexes is cortical, that for the body righting reflexes acting upon the head have their centers in the neighborhood of but not in the red nucleus itself (Magnus).

(b) *The stato-tonic labyrinthine reflexes* acting upon the skeletal muscles have the center in the vestibular nuclei.

(c) *The neck reflexes* are centered in the upper two or three cervical segments of the cord (see fig. 349).

FIG. 349. Diagram to illustrate the effects of sections through cat's brain at various levels. Line I, thalamic animal, righting, tonic labyrinthine and neck reflexes retained; little disturbance of muscular tone; Lines II and III, decerebrate rigidity; Line IV, behind vestibular nucleus, decapitate animal, extensor rigidity abolished, tonic neck reflexes retained. Section at level of second or third cervical segment of the cord—spinal animal—abolishes the tonic neck reflexes (after Magnus).

(d) The centers for the *tonic labyrinthine and cervical reflexes acting upon the eyes* are situated between the vestibular nuclei and the nuclei of the nerves to the eye muscles.

LOCAL STATIC REACTIONS. SUPPORTING REACTIONS

Magnus speaks of the simultaneous reflex contractions of extensor and flexor muscles and other opposing muscles whereby the joints are fixed and the limbs converted into rigid pillars for the support of the body against gravity as the *positive*

⁷ The conclusion that the red nucleus is the essential center for the labyrinthine righting reflexes has been recently contested. Keller and Hare found that sectioning the rubrospinal tracts did not abolish them. (See also, Ranson and associates.)

supporting reaction. This reaction is initiated by:—

(a) Impulses discharged from the proprioceptors of the flexor muscles of the terminal segments of the limbs—digits and ankle or wrist; the pressure of an animal's paw upon the ground by stretching these muscles provides the adequate stimulus which calls forth simultaneous reflex contractions of the flexors and extensors of the knee (or elbow).

(b) Myotatic reflexes set up in the flexors of ankle and toes (plantar flexors) or of the terminal joints of the forelimb; excessive extension at these joints is thus counteracted. Any tendency toward over-extension at the knee or elbow is also provided against through the reflex set up when the flexors of these joints are stretched. Similarly, any tendency of the knee or elbow to bend under the weight of the body calls forth a myotatic reflex from the extensors, which prevents any weakening of the supporting action of the limb.

(c) Impulses set up in the pressure receptors in the deeper layers of the skin of the sole when in contact with the ground; thus exteroceptive reflexes reinforce those of proprioceptive origin. The exteroceptor element is well shown in a decerebellated dog. When such a preparation is placed upon its back and the head strongly flexed, the hind limbs are flexed in all joints. Light pressure with the finger upon the toe pad then causes an extension of the limb, and if the finger be moved with the limb as it extends so that only very light pressure upon the pad is maintained, one has the sensation of the limb being drawn out by the finger. For this reason the movement has been called the "magnet reaction."

The relaxation of the muscles and the unfixing of the joints which enables the limb to be flexed and moved to a new position is called the *negative supporting reaction*. It is brought about by raising the pad off the ground and plantar flexing the toes and ankle. The exteroceptive stimulus and the stretch stimulus to the *plantar flexors* are thus removed. The reflex "unlocking" of the limb is not, however, simply due to the removal of these stimuli, but has in addition a positive element, namely, the stimulus provided by the stretching of the dorsi-flexors of the toes and ankle—relaxation of the extensors of the knee or elbow and contraction of the flexors result.

The supporting reactions, though seen best in a decerebellate animal, can also be demonstrated in the decorticate preparation or in one whose brain-stem has been divided above the medulla oblongata. Segmental static reactions, e.g., flexion

reflex and the crossed extension reflex have been described in Chapter LXV.

Placing and hopping reactions. These were first studied by Rademaker and have been more recently investigated by Bard. Bard and Brooks describe five *placing reactions*.

(1) If a cat is held in mid-air with legs dependent and chin held up so that it cannot see anything below or in front, contact of the backs of the forepaws with the table's edge is followed by a quick movement of the limbs which brings the paws, soles down, precisely upon the surface of the table. (2) If the forelimbs of a cat are held down while the chin is brought in contact with the table near its edge, the forepaws when released are instantly raised and placed upon the table beside the chin, a movement which is usually accompanied by extension of the limbs and the assumption of a standing position. (3) If the fore- or hindlimbs of a cat standing or sitting upon a table are pushed over the table's edge, they are immediately lifted and placed in their original positions. (4) If one abducts, without holding, the limb of a standing cat, it is instantly returned to its previous position. (5) If a blind-folded cat is suspended in the air with forelimbs free, and its head brought toward some obstacle, at the instant that the vibrissae come into contact with the object, the forepaws are raised and accurately planted upon its surface. The first three of these reactions are due to stimulation of receptors upon the body surface (exteroceptors) and probably also of proprioceptors in muscles and tendons. The fourth is a purely proprioceptive reflex; the last is initiated from tactile receptors. The *hopping reactions* consist of limb movements which serve to maintain the standing position against any force acting upon it in a horizontal plane. When, for example, a cat is held so that its body is supported upon one fore- or hindlimb and is then pushed in one or other direction, the supporting limb hops quickly in the direction of the displacement, the foot being kept directly under the corresponding shoulder or hip. The hopping reactions are probably dependent upon myotatic (stretch) reflexes (p. 822).

The placing and hopping reactions are controlled from the sensorimotor area of the cerebral cortex. Removal of this region by Bard and Brooks on both sides was found to abolish the placing reactions, and to produce an extreme degree of deficiency in the hopping reactions. Decortication (complete removal of the neocortex) produced no greater deficiency. The control exerted by the cerebral cortex is entirely contralateral, i.e., the component movements of the reactions on one side of the body are governed solely by the opposite side of the brain.

STATO-KINETIC REFLEXES

ANATOMY OF THE LABYRINTH

Before a description of other labyrinthine functions, e.g., the stato-kinetic reflexes, can be undertaken, a

brief description of the structure of the labyrinth must be given. This structure consists of an auditory (cochlear) and a non-auditory portion. We are concerned here only with the latter which we shall refer to simply as the labyrinth. The *bony labyrinth* comprises a series of cavities tunnelled in the petrous part of the temporal bone. The cavities are the three semicircular canals, each of which opens by its two extremities into an ovoid chamber known as the *vestibule*. The bony labyrinth lodges a series of hollow membranous structures—the *membranous labyrinth*. The membranous labyrinth consists of: (a) *Three semicircular canals* lying in the corresponding bony canals. (b) Two sacs, the *utricle* and *sacculle* situated in the vestibule.

THE SEMICIRCULAR CANALS. One extremity of each canal shows an expansion known as the *ampulla* wherein is situated the specific sense organ. The membranous labyrinth is filled with fluid—the *endo-*

FIG 350. Diagram showing the semicircular canals and their relation to the planes of the skull. S, sagittal plane; F, frontal plane (see text).

lymph: a similar fluid—the *perilymph*—lies between its walls and the walls of the bony labyrinth. The canals lie in planes approximately at right angles to one another and are called respectively *external* (horizontal), *anterior* (vertical) and *posterior* (vertical) (see fig. 350). It will be noted that the non-expanded extremities of the vertical canals join to form a common stem through which they communicate with the utricle (fig. 352).

The external canal is directed with its convexity outwards and backwards. When the head is in the erect position this canal is only approximately horizontal; it is inclined backwards and downwards at an angle of about 30° to the horizontal plane. The vertical (anterior and posterior) canals both make an angle of 45° with the frontal and the sagittal planes of the skull.⁸ The anterior canal of one ear is therefore in the same plane as the posterior canal of the other ear,

⁸ That is, their planes cross both the frontal and sagittal planes diagonally.

whereas the posterior or anterior canal of one ear is at right angles to its fellow of the opposite side as well as to the other two canals of the same ear. The external (horizontal) canals of the two sides lie in the same plane.

THE CRISTA. This is the receptor organ of the semicircular canal. It is situated in the ampulla and

FIG. 351. Cardboard model with the skull of a monkey, to show the planes of the utricle and saccule with respect to the skull (from Camis after de Burlet and Haas).

FIG. 352. Diagram (not to scale) giving a lateral view of the internal ear within the skull. V, vertical canals; H, horizontal canal; U, utricle; S, sacculle; C, cochlea (redrawn from Quix).

consists of a mound of sensory hair cells between which are non-sensory supporting cells. The sensory cells are surmounted by a gelatinous dome-shaped structure—the *cupola*; this contains fine longitudinal channels in which the hairs or cilia are lodged.

THE OTOLITH ORGANS—THE UTRICLE AND SACCULE. In the wall of the *utricle* lie the openings of the semicircular canals. It also communicates with the sacculle by a small canal—the *ductus endolymphaticus*. The sense organ of the utricle is called the *macula*. This

consists of a plaque of sensitive hair cells covered by a layer of gelatinous material (otolith membrane) upon which are situated crystals or small concretions of lime—the *otoliths*. The *saccul*e communicates with the utricle on the one hand and with the cochlea on the other. Its communication with the latter is through the duct of Henson. The sense organ of the saccul is also given the name of *macula*^o and is constructed upon a plan similar to that of the utricle. The macula

are in the same plane, whereas the *saccular macula* are in different planes, forming an angle opening forwards and downwards (figs. 351 and 352).

THE NERVOUS CONNECTIONS OF THE LABYRINTH

The impulses from the proprioceptors of the different parts of the non-auditory labyrinth are conveyed to the medulla by the vestibular branch of the 8th nerve

FIG. 353. Diagram of vestibular pathways (see text).

of the utricle is approximately horizontal, sloping slightly downwards and backwards, its front part being curved upwards like the prow of a boat. The saccular macula is roughly vertical, sloping from behind forwards and outwards and from below upwards and inwards. The utricular maculae of the two ears

^oThe term "lapillus" is sometimes applied to the otolithic organ of the utricle while that of the saccul is spoken of as the "sagitta."

The cell bodies of the vestibular fibers lie in Scarpa's ganglion. They pass for the most part to the *vestibular nuclei* in the medulla from which relay fibers follow three pathways (fig. 353). Thus there are:

- (a) Ascending fibers which join the medial longitudinal bundle of the same and opposite sides and pass to the nuclei of the 3rd, 4th and 6th cranial nerves (vestibulo-ocular tract). Through these connections reflex movements of the eyes are brought about.

(b) Descending fibers, constituting the vestibulo-spinal tract, connect with the spinal motor neurons. Through these connections impulses are conveyed to the skeletal muscles.

(c) Fibers which pass to the cerebellar nuclei (N. globosus, emboliformis and fastigii) via the inferior cerebellar peduncle and thence to the cerebellar cortex. These constitute the vestibulo-cerebellar tract. Impulses conveyed along this pathway and thence through the superior cerebellar peduncle to the cerebrum give rise to the sensation of vertigo.

As a result of his clinical findings I. H. Jones concludes that the fibers from the vertical and from the horizontal canals follow different paths. Those from the vertical canals do not according to this observer, enter the vestibular nuclei but ascend to the pons where they divide into two diverging paths; one arm of the Y so formed joins the medial longitudinal bundle and is distributed to the ocular nuclei; the other passes to the cerebellar nuclei via the middle cerebellar peduncle.

EFFECTS FOLLOWING LABYRINTHECTOMY (IN THE DOG)

Unilateral labyrinthectomy. (1) *Ocular.* Both eyes are turned toward the side of the operation. The eye of this side also shows a downward deviation while the eye of the sound side deviates upwards (skew deviation). *Horizontal nystagmus* (p. 839) with the slow movement toward the operated side.

(2) *Lateral flexion and rotation of the occiput* to the operated side together with flexion of the thorax on the pelvis toward this side.

(3) *The extensor tone of the limb muscles* is greater on the sound side than on the operated side, the limbs of this side being flexed and adducted, whereas those of the opposite side are extended and abducted.

(4) *Spontaneous movements.* These are all toward the operated side and consist of (a) circling, i.e., turning of the body around a vertical axis, (b) rolling, i.e., rotation around a horizontal axis; in the rabbit the rolling movements are very violent, (c) side to side movements of the head (head nystagmus), (d) falling to operated side, (e) stepping gait.

Many of the foregoing features, e.g., nystagmus, rolling and circling movements, are *irritative* in nature, i.e., the result of irritation of nerve endings by the operative trauma. They therefore improve with time. The others, e.g., oscillating movements of the head, head torsion, stepping gait, falling and asymmetrical distribution of

tone, are deficiency phenomena.¹⁰ These, for the most part, also improve since they tend to be compensated by visual and other non-labyrinthine reflexes, especially in higher animals, who also learn to exercise cerebral control over the abnormal muscular activity.

Bilateral labyrinthectomy produces irritative effects similar to those described above, the direction of the movements being variable and dependent upon which ear shows the greatest degree of irritation. The labyrinthine static reflexes are, of course, abolished but in the more intelligent animals the defects of orientation are largely compensated for by visual reactions. The normal reactions to rotation (p. 839) are abolished.

AN ANALYSIS OF LABYRINTHINE FUNCTION

The *cristae* of the semicircular canals are organs of *kinetic sense* and are responsible for the compensatory movements of eyes and limbs—stato-kinetic reflexes—to be described. The macula of the utricle is an organ of *static sense*. Upon it depend the righting and stato-tonic reflexes. The cristae of the canals respond only to changes in *velocity* (acceleration or retardation) of a rectilinear motion or to changes in *direction* of a movement, i.e., any curvilinear motion (angular acceleration). Uniform movement produces no labyrinthine reaction or any sensation. For example, when one travels with closed eyes in a straight line and perfectly smoothly, i.e., in the absence of changes in velocity which would cause jolts, the motion is unperceived. A sensation is at once aroused by a change in speed, provided that it occurs with a certain degree of suddenness; and a reflex muscular movement may result. A sensation is also aroused if the line of travel curves to one or other side, upward or downward. Tait and McNally found that in the frog, the movement to be effective must occur above a certain minimum speed, a slow rotation or tilting was not followed by a compensatory reaction.

Stimulation of the sensitive hair cells of the cristae is brought about through the effect which the movement of the head exerts upon the endolymph within the canal. The canals are stimulated by a rotation of the head in their respective planes but not by rotation in other planes; thus

¹⁰ Cocaine injected into the labyrinth produces the deficiency phenomena characteristic of labyrinthectomy, but when applied to the nerve stump after removal of the labyrinth it prevents the occurrence of the irritative phenomena.

the horizontal canals are stimulated by rotation in the horizontal plane, the vertical canals by rotation in the sagittal or frontal plane.

The canals are of capillary size (0.1 to 0.2 mm. in diameter in man) and the endolymph is of relatively high viscosity (2 to 3 times that of water). The membranous labyrinth is a practically closed system and is supported on the outside by perilymph, and the unyielding walls of the osseous labyrinth. These facts would seem to preclude the possibility that any current could be set up in the endolymph by a linear movement of the head which could act as a stimulus to the hair cells. On the other hand, a rotary movement of the head might possibly set up a current since each canal, through its communication with the utricle, constitutes virtually a circular system. Nevertheless, models made upon the plan of the canals and filled with fluid and then rotated do not show any

FIG. 354. Position taken up by a frog placed on a rotating disc during rotation to the left (from Camis after Ewald).

movement of the fluid in the nature of a continuous current. It was found, however, that as a result of its inertia a slight displacement of the fluid in relation to the walls of the tube occurred during rotation. The displacement, of course, was in a direction opposite to that of the rotary movement. When the motion was abruptly stopped, the fluid as a result of its momentum exhibited a displacement in the reverse direction, i.e., in the same direction as the previous rotation. Direct observations of the endolymph in the living animal after the introduction of a few particles of lamp black into the canal also revealed displacement during and at the end of rotation. It is concluded therefore that the pressure changes resulting from such displacements of the endolymph provide the adequate stimuli for the hair cells of the cristae. (See also Ewald's Experiment, p. 845).

A differentiation of the functions of the two sets of canals (horizontal and vertical) has been made possible by the experiments of McNally and Tait.

Working with frogs, these observers succeeded in denervating all six canals without damage to other parts of the labyrinth. Denervation of the canals individually and in pairs was also performed. They found that after the function of the canal system on both sides had been completely abolished, the animal assumed a normal posture manifesting no forced movements or disturbance of equilibrium if left undisturbed. However, a quick rotary movement around a vertical, transverse or antero-posterior axis did not cause the usual compensatory reactions of the head and limbs. A rotary movement around a transverse or antero-posterior axis is caused by tilting a table upon which an animal is resting forward or backward, or sideways. McNally and Tait conclude as a result of their experiments that the horizontal canals respond only to angular acceleration in the horizontal plane, a particular canal being stimulated when its *unexpanded portion* is advancing and its ampulla bringing up the rear; the vertical canals respond to angular acceleration in their respective planes as well as to linear acceleration, as by a movement forward, backward or sideways of the surface upon which the animal is resting; a given canal is stimulated most powerfully when the *ampullary end* is advancing.

Stimulation of a horizontal canal affects the musculature of both sides of the body and thus enables the body to resist being turned to one or other side. When, for example, an animal such as the frog (see fig. 354) is rotated to the left around a vertical axis the head turns to the right; the limbs of the left side are at the same time extended while those of the right side are flexed. The animal may walk around toward the right, that is, in a direction opposed to that of the rotary movement.

The muscular response following stimulation of a vertical canal is confined to one side of the body. Each of the four vertical canals when stimulated by tilting the animal, in the appropriate plane, causes contraction of the muscles of the corresponding quarter or "corner" of the body. Thus stimulation of the left anterior vertical canal, as by tilting diagonally forward and to the left (displacement of endolymph away from ampulla), causes contraction of the muscles of the left forelimb. The left posterior canal is concerned with movements of the left hind limb; stimulation of the right vertical canals govern in a corresponding manner the limb muscles of the right side. The vertical canals thus serve to maintain the normal orientation of the head in relation to the horizontal plane.

By causing contraction of the musculature of the appropriate limbs they counteract a force tending to upset the body in a forward, backward or lateral direction, i.e., they prevent rotation of the body in a vertical plane and thus keep it upon an "even keel."

The maculae. By centrifuging a guinea pig (at a rate of 1,000 to 2,000 revolutions per minute) it is possible to detach the otolithic membranes. An animal so deprived of its otolithic organs retains its labyrinthine reactions resulting from acceleration (stato-kinetic reflexes), but has lost its stato-tonic reflexes. McNally and Tait also found that unilateral injury of the utricle caused loss of muscular tone upon that side, the limbs becoming flexed. The body is curved and the head inclined to the injured side. The limbs of the opposite side are extended and the animal makes forced circling movements toward the side of the injury. A bilateral utricular injury resulted in great impairment of the righting reflexes, the animal being unable to maintain the normal position of the body against gravity. On the other hand, functional ablation of the semicircular canals causes no disturbance of the static postural reactions.¹¹ The adequate stimulus for the *utricular maculae* is, apparently, a gravitational pull of the otolithic membrane away from the hair cells. The maximal tonic effect upon the extensor muscles is exerted when the animal is supine with head extended, i.e., when the maculae are horizontal with the otoliths hanging from the hair cells. The minimal tonic effect is exerted when the animal is prone with head flexed (p. 831), i.e., when the maculae are horizontal with the otoliths resting upon the hair cells. The functions of the *saccular maculae* are not definitely known. McNally and Tait denervated the saccular maculae of the frog but observed no disturbance of either static or dynamic postural reactions. Parker and later Maxwell destroyed the saccules in the dog fish but no disturbance of equilibrium resulted. De Kleijn and Versteegh succeeded in destroying both saccules in the rabbit, after which all the labyrinthine reflexes could be evoked. This part of the labyrinth is possibly associated with cochlear rather than with

postural function. Tait suggests that it is an organ for the registration of vibrations in the head, i.e., vibration through bone as distinct from vibration through air. The appreciation of the sound of one's own voice may possibly depend therefore upon saccular as well as upon cochlear function.

The following is a *summary* of the respective functions of the canals and utricular maculae.

(a) *Semicircular canals*, i.e., the cristae of the ampullae, are responsible for the reactions resulting from a rectilinear or rotary *movement*, e.g., the compensatory *movements* of the eyes (see below) and limbs. (b) The *utricular maculae* are responsible for the reactions resulting from *position*, e.g., labyrinthine stato-tonic reflexes, righting reflexes and for the compensatory *positions* of the eyes. Utricular impulses serve to maintain the position already induced by stimulation of the canals.

METHODS OF STIMULATING THE LABYRINTH

In order to demonstrate the stato-kinetic reactions in animals, the semicircular canals may be excited by any one of the following modes of stimulation: (1) Rotation of the body. (2) Caloric—syringing the ear with hot or cold water. (3) Galvanic. (4) Mechanical. The first three of these means of stimulation are applicable to man.

(1) Rotation

The threshold for the perception of rotation is from 1° to 2° acceleration per second.

Rotary excitation of the canals results in four groups of reflex effects: (a) nystagmus, (b) vertigo, (c) reactions of the limbs and body, (d) reactions of the autonomic nervous system.

(a) NYSTAGMUS. If a normal person is rotated rapidly (10 turns in 10 seconds) on a revolving chair with the eyes closed, an involuntary rhythmic movement of the eyes is seen when the motion is stopped and the subject opens his eyes. The oscillation of the eyes, which is called nystagmus, lasts for about 20 seconds (normal range 15 to 35 seconds). (Nystagmus may also be induced by caloric or galvanic stimulation of the canals or may result when the eyes attempt to "fix" rapidly moving objects, as in looking from a moving vehicle.) Nystagmus consists of two components, a slow movement in one direction and a rapid movement (jerk) which returns the eye to the primary position, i.e., to its normal forward-looking position. In the nystagmus of vestibular origin the slow movement is a reflex (stato-kinetic) resulting from stimulation of the semicircular canals and is an

¹¹ The otocyst of the prawn is homologous to the utricle of mammals. It is open to the exterior and at moulting time its lining is shed. The otoliths consist of grains of sand which the animal itself introduces into the otocyst. If, after moulting, the animals are placed in a dish containing fine iron filings these are inserted and various forced movements of the head and body can be induced by bringing a magnet into relation with the ear.

attempt to keep the visual fields fixed when the head is moved (p. 833). The rapid component is cerebral in origin; the cortical centers recognizing, as it were, the deviation of the eyes and their false position in relation to the head, bring them back each time to the correct position. Under anesthesia the rapid component disappears, the

of the horizontal and rotary forms; up or down in the vertical type. The rapid, not the slow (vestibular), component is used to indicate the direction of the nystagmus. Thus, a horizontal movement with the rapid component to the subject's right is spoken of as a *right* horizontal nystagmus; one with the rapid component to the subject's left is spoken of as a *left* horizontal nystagmus.

When a subject is rotated, the movement causes a displacement of the endolymph in those canals which are in, or nearly in, the plane of rotation. When, for instance, the head is bent forward 30° the external (horizontal) canals are actually horizontal (fig. 355) and for the first 10 turns or so the endolymph is displaced in a direction opposite to that in which the canal is moving. Thus,

FIG. 355. Positions during rotation. Upper, horizontal canals in plane of rotation. Lower, vertical canals in plane of rotation. V, vertical canals; H, horizontal canal.

vestibular component then producing a sustained deviation in one or other direction.

Nystagmus is of three varieties, (a) *horizontal* in which the eyes move from side to side, i.e., in a horizontal plane, (b) *vertical* in which they move upwards and downwards, i.e., in the sagittal plane of the skull, and (c) *rotary* with the eye movement in the frontal plane of the skull. The rapid component may be to the right or left in the case

After this, the inertia or lag of the endolymph is overcome; fluid and canal move together. Upon stopping the rotation, the momentum of the endolymph causes it to move in relation to the wall of the canal in a direction opposite to that of its initial displacement, i.e., in the direction of the preceding rotation. Horizontal nystagmus results.

It should be mentioned that owing to the reversed position of the two external canals in relation to the direction of rotation, the endolymph is displaced toward the ampulla of one canal but away from the ampulla of the other. The direction of the slow movement of the nystagmus, it will also be noted,

is the same as that of the endolymph displacement. The rapid movement is of course in the opposite direction.

Vertical nystagmus (i.e., movement of eyes in the sagittal plane) results when the rotation is carried out with the head flexed to one or other shoulder at an angle of 90° so as to bring the vertical canals nearly into the plane of rotation; the head is thus rotated in the sagittal plane. Rotary nystagmus (movement of eyes in frontal plane) is induced by rotation with the head bent forward 120° or backward 60° , the head being then rotated in the frontal plane (fig. 355).¹² The effects of rotation upon the ampullae of the vertical canals in these different positions of the head are most complicated; the eye reactions represent the resultant of the effects in all four canals and cannot be analyzed in detail here. It is to be remembered that since the vertical canals are joined by a common stem one cannot be influenced entirely independently of the other.

In connection with the production of post-rotary nystagmus the following general rules may be summarized.

(1) The slow (vestibular) movement of the eyes after rotation has the same direction as that of the endolymph displacement, i.e., of the previous rotary movement. The rapid movement is then, of course, opposite in direction to that of the rotation. The crista of a horizontal canal, though stimulated by an endolymph movement away from it, is stimulated much more powerfully by a movement of the fluid towards it.

(2) The cristae of the vertical canals are stimulated by an endolymph displacement in either direction, but more powerfully by one *away* from the ampulla.

(3) The horizontal canals of the two sides are in the same plane. The anterior vertical canal of one side is in the same plane with the posterior vertical canal of the opposite side. The vertical canals of the same name (anterior or posterior) on the two sides or of different names on the same side are in different planes.

(4) The pressure of the endolymph in two canals in the *same* plane (e.g., horizontal canals or an anterior and a posterior vertical canal of opposite sides) is in opposite directions (toward the crista in one ear and away from it in the opposite ear).

(5) The pressure of the endolymph in any two vertical canals in *different* planes may be in the same or in opposite directions (i.e., toward or away from the cristae), depending upon the position of the head during rotation.

¹² This is of course equivalent to rotating the body around its antero-posterior axis (in the frontal plane of the skull) when the head is in its normal relation to the trunk.

(6) The horizontal canals are connected with the internal and external recti; the anterior vertical canals with the inferior and superior recti; the posterior vertical canals with the inferior and superior obliques.

(7) Stimuli of opposite sign (i.e., pressure toward the crista of one canal and away from the crista of the other) in two canals in the same plane act synergically. For example, if the endolymph moves toward the ampulla of the left horizontal canal and away from that of the right canal, the internal rectus of the left eye and the external rectus of the right eye contract while their antagonists relax—reciprocal innervation; slow movement of the eyes to the subject's right occurs (diagram p. 840).

(8) Stimuli of the same sign in a pair of vertical canals in different planes (e.g., in anterior and posterior canals of the same side or canals of the same name of opposite sides) act antagonistically—they tend to counteract one another's effects.

(9) In stimulation of the vertical canals, (a) if the pressures in each unilateral pair of vertical canals (anterior and posterior of the same side) are opposite in direction in relation to the cristae, but in the same direction in each bilateral pair of canals (the two anterior or the two posterior canals of opposite sides) the nystagmus is vertical. This occurs when the subject is rotated with head on one shoulder. (b) When the pressures in a unilateral pair are in the same direction in relation to the cristae but opposite in direction in the bilateral pairs the nystagmus is rotary. This occurs when the subject is rotated with head forward 120° or backward 60° . (See table 77.)

(b) VERTIGO. Vertigo consists of the familiar whirling sensation or giddiness, and the disturbances of equilibrium which follow spinning. When the subject is rotated with head erect, his vertigo is in the horizontal plane, i.e., in the plane of the external canals but in the direction opposite to that of the previous rotation (sensation of counter-rotation); it is therefore *in the opposite direction to that of the endolymph movement and of the slow (vestibular) movement of the post-rotary nystagmus*. The surrounding objects appear to the subject to whirl around with him, i.e., in the same direction as that of his own sensation of rotation.

If the subject is rotated with the head bowed forward at an angle of 120° (fig. 355, p. 840) to bring the vertical canals into the plane of rotation, and the head maintained in this position after rotation, the sensation is the same as if the head position had been upright during rotation, i.e., one of counter-rotation. If, however, the head is brought upright after rotation there is then a sensation of falling to one or the other side, i.e., of rotation of the body in the frontal plane; the sensation is of falling to the side away from that

TABLE 77

POSITION OF HEAD	STIMULUS	ENDOLYMPH DISPLACEMENT IN HORIZONTAL CANALS		TYPE AND DIRECTION OF NYSTAGMUS (RAPID PHASE)	SENSATION OF VERTIGO, HEAD UPRIGHT AFTER ROTATION	PAST- POINTING	FALLING (AFTER BRINGING HEAD UPRIGHT)
		RIGAT	LEFT				
Upward or forward	Rotation to right 			Horizontal, left	Turning left	To right	
	Rotation to left 			Horizontal, right	Turning right	To left	
Backward 60°	Rotation to right 			Rotary, right	Falling right to	To left	To left
	Rotation to left 			Rotary, left	Falling left to	To right	To right
Forward 120°	Rotation to right 			Rotary, left	Falling left to	To right	To right
	Rotation to left 			Rotary, right	Falling right to	To left	To left
Inclined to right shoulder	Rotation to right 			Vertical, downward	Falling forward	Upward	Backward
	Rotation to left 			Vertical, upward	Falling backward	Down- ward	Forward
Inclined to left shoulder	Rotation to right 			Vertical, upward	Falling backward	Down- ward	Forward
	Rotation to left 			Vertical, downward	Falling forward	Upward	Backward

TABLE 77—Continued

Backward 60°	Caloric 112°F. to right ear or 68°F. to left.		Horizontal, right	Falling to right	To left	To left
Forward	Caloric 112°F. to left ear or 68°F. to left.		Horizontal, left	Falling to left	To right	To right
	Galvanic		Mixture of horizontal and rotary. Direction same as that of current. The responses occur only during the passage of the current.			

As an aid to memory it may be pointed out that in the erect, or forward position of the head the slow (vestibular) phase of the nystagmus and the past pointing are in the same direction as that of the rotation, i.e. in the direction of the endolymph displacement at the end of rotation. The rapid phase and the vertigo are in a direction opposite to that of the rotation, i.e. against the endolymph movement. Caloric stimulation with the head upright causes a rotary nystagmus with its direction away from the side of the syringed ear, in the case of cold douching, and toward this side in the case of hot douching. The sensation of falling is in the same direction as the nystagmus, while the past pointing and actual falling are in the opposite direction i.e., to the side of the syringed ear with cold douching and away from it with hot douching. In the above table, right and left means the patient's right and left sides.

toward which the body had been rotated. Rotation with the head bent backwards to an angle of 60° and then brought upright gives a sensation of falling to the same side as that toward which the body had been rotated (see table 77). A sensation of falling forward or backward (i.e., rotation in the sagittal plane) results from rotation with the head flexed on one shoulder and then brought upright.

Vertigo therefore differs from nystagmus which is not affected by the post-rotary position of the head. The reason for this difference is that, whereas nystagmus is reflex, the sensations of vertigo are largely the result of cerebral interpretation of endolymph movement and the position of the head at the moment is taken into account. The cerebral cortex through past experience has associated a displacement of endolymph in one direction with a movement of the head in the opposite direction; a post-rotary displacement of endolymph to the left in the horizontal canals is, therefore interpreted as a turn of the head to the right, and vice versa. Similarly, a post-rotary movement of endolymph in the vertical canals while the head is upright is interpreted as a rotation of the body in the frontal or in the sagittal plane (falling to one side or forward or backward), according to the position of the head during the rotation, for in the ordinary upright position the receptors in the vertical canals are stimulated in the same manner by a movement of the head in the respective plane.

Vertigo arises from other causes than rotation. It occurs as a result of alcoholic intoxication, sea-sickness, swinging, etc. Also, just as the labyrinth influences the movements of the ocular muscles, so, conversely, labyrinthine function may be disturbed and vertigo produced as a result of some unusual or abnormal action of the eye muscles. Vertigo and its associated phenomena are, therefore, common effects of eye strain or of viewing the landscape from a moving train; an ocular element is also an important contributory factor in the causation of sea-sickness. It should also be emphasized that with whatever condition vertigo is associated, whether cardiovascular, renal, toxic, gastrointestinal or neurological, its immediate cause is excitation of the semicircular canals or of their central connections.

(C) POST-ROTARY REACTIONS OF THE LIMBS AND BODY.

The past-pointing test of Barany. Under ordinary circumstances a normal person if he places his finger upon a certain spot has no difficulty in hitting the mark again with his eyes closed. After rotation, though able to place his finger upon a mark with his eyes open, he cannot find it again when his eyes are closed. The finger *deviates* or

past-points to one or other side, or above or below the mark, the direction of the miss-aim being dependent upon the direction of the previous rotation and upon the position of the head during rotation (see table 77). Past-pointing is not reflex in nature but is a voluntary motor act, the error in judgment is the result of the associated subjective phenomenon of vertigo, a subconscious correction being made in the opposite direction for the false sensation. The deviation of the finger and the vertigo are therefore in opposite directions, the former being toward the same side as the slow movement of the nystagmus, i.e., *in the direction of the endolymph displacement*.

Other post-rotary reactions. If the body is rotated in the plane of the horizontal canals and the movement stopped, the head (eyes closed) then turns in the direction of the rotation. If rotation

FIG. 356. So-called 'discobolus' position resulting from caloric or galvanic excitation of the labyrinth (from Camis after Wodak and Fischer).

is carried out with the head in one or other plane of the vertical canals and the head after rotation is brought upright while the eyes are closed, the body leans to one or other side, backward or forward, according to the position of the head during rotation. The subject may actually fall in the direction to which the body leans. The phenomenon is virtually a past-pointing of the entire body. The actual fall is, therefore, opposite in direction to the vertiginous sensation of falling. That is, the subject leans from the erect position in an effort to counteract the false sensation of falling in the opposite direction.

One particularly interesting reaction resulting from excitation of the semicircular canals is that which has been appropriately called the *discobolus* attitude (fig. 356). Though occurring after rotation it is evoked most readily by caloric (especially

cold) or galvanic stimulation of the canals. stimulus applied, say to the left ear, causes twisting of the thorax upon the pelvis and rotation of the head to the stimulated side. When the arms are raised they are also turned toward the side with the left limb lower than the right. After a short time the attitude is reversed, the body swings round and takes up a position in the opposite direction. The attitude may reverse its direction several times. It is due to reflex alterations in tone of the musculature on the two sides of the body.

(d) REACTIONS OF THE AUTONOMIC NERVOUS SYSTEM. Excitation of the semicircular canals in man is not uncommonly followed by nausea, vomiting and pallor. A fall in blood pressure of 10 mm. or so may occur, together with slowing of the heart by 8 or 10 beats per minute. In the rabbit, syringing the ear causes vasodilatation and a fall in blood pressure. During rotation the pupil constricts; pupillary dilatation occurs upon cessation of the rotary movement.

Camis has shown that after labyrinthectomy, the usual effect upon blood pressure of stimulating the central end of the vagus is reversed. For example, the effect of stimulating the central end of the vagus in the normal dog is frequently a rise in blood pressure accompanied by vasoconstriction of the vessels of the hind limb. After unilateral labyrinthectomy stimulation of the central end of the vagus on the operated side causes a fall in blood pressure together with a reduction of limb volume on the same side. Stimulation of the vagus in a bilaterally labyrinthectomized animal results in a fall in blood pressure and a reduction in volume of both limbs—a relationship between blood pressure and limb volume which is the reverse of the normal (p. 251). There is no satisfactory explanation of these paradoxical reactions. Camis suggests that labyrinthectomy abolishes the activity of the vasoconstrictor center. Stimulation of the central end of the vagus would then result in pure vasodilator effects, and a fall in blood pressure. The reduction in the volume of the limb may be simply a passive effect—the drainage of blood from its vessels. Bayliss found, for example, that after removal of the abdominal sympathetic (constrictors to the vessels of the abdomen, and hind limbs), a fall in blood pressure, accompanied by a reduction in limb volume resulted from stimulation of the central end of the vagus.

(2) Caloric stimulation

The effects of caloric stimulation are similar to those following rotation but possess an advantage in that one or other ear can be examined separately. The ear to be tested is syringed with hot (112°F.) or with cold

68°F.) water.¹³ When the head is bent backward through 60° the horizontal canals are brought into a vertical position. The douche causes a greater change in the temperature of the endolymph in the part of the canal lying nearer to the external meatus than in the part more deeply situated. Convection currents are set up which stimulate the crista and horizontal nystagmus and vertigo result. The change in temperature in the canal follows the irrigation of the external meatus by about 3 seconds. The direction of the convection currents, which of course are due to changes in the specific gravity of the endolymph resulting from heating or cooling, is determined by the temperature of the douche fluid. Thus a cold douche causes currents away from the ampulla, a hot douche causes ones toward the ampulla (see table 77). Caloric stimulation of the vertical canals is effected by douching with the head upright.

(3) Galvanic stimulation

In the employment of this method of stimulating the canals electrodes are placed one upon each mastoid process or, more usually, one on a mastoid process and the other on some indifferent part of the body. The current required in normal persons is from 2 to 7 milliamperes. Nerve endings in all six canals are excited by galvanic stimulation. The resulting nystagmus is a mixture of the horizontal and rotary forms, its direction being the same as that of the current. Thus, when the cathode is on the right the nystagmus is to the right and vice versa. The effects occur only during the make and break of the current. In the absence of the labyrinth the galvanic current produces its effects by stimulation of the vestibular nerve. Consequently when, as the result of disease, labyrinthine function has been destroyed, this method affords a means of determining the condition of the nerve.

(4) Direct mechanical stimulation of the canals in animals

Ewald cemented a metal cylinder over a hole made in the bony wall of the horizontal canal. A piston fitted into the cylinder could be operated by air pressure. During the descent and ascent of the pneumatic hammer the membranous canal was compressed and decompressed respectively. The endolymph during compression and decompression moved, respectively, toward and away from the ampulla. An endolymph movement toward the ampulla caused a movement of the head and eyes to the opposite side. Decompression caused a weaker movement in the reverse direction.

VESTIBULAR REACTIONS IN DISEASE

Abnormal vestibular reactions are seen in various diseased conditions involving (a) the laby-

¹³ Douches much nearer the body temperature than these will stimulate.

rinth, (b) the vestibular nerve, or (c) the vestibular centers or central pathways (e.g., Deiter's nucleus, medial longitudinal bundle, cerebellum). Normally, some slight nystagmus may occur upon looking for a time to the right or left, but if nystagmus is present when looking forward or if pronounced when the eyes are turned to one side, it is pathological. A spontaneous vertical nystagmus suggests a lesion of the brain stem; it is not seen in disease of the labyrinth itself or of the vestibular nerve. The phenomenon of past-pointing, unless induced artificially, is always pathological and suggests a cerebellar lesion. Spontaneous vertigo and falling in one or other direction may result from disease of the cerebellum, the labyrinth or the pathways of the vestibular fibers. On the other hand, a lesion in one or other of these situations may cause a failure of the usual reactions following rotary or caloric stimulation. In deaf mutes, the labyrinthine reactions, as a rule, are absent. Again, the reactions to artificial stimulation may be abnormal; for example, in a lesion of the brain stem vertical nystagmus may occur in response to a stimulus which normally causes nystagmus of the horizontal type.

The following is a summary of the abnormal labyrinthine reactions with their diagnostic significance, as given by Fisher.

I. *If stimulation of a horizontal canal of one ear, (1) causes nystagmus (normal) but not vertigo, past-pointing or falling, a lesion of the inferior cerebellar peduncle of that side is suggested, (2) causes vertigo, past-pointing and falling (all normal) but not nystagmus, a lesion between Deiter's nucleus and the medial longitudinal bundle of that side is suggested.*

II. *If stimulation of the vertical canals of one ear, (1) causes nystagmus (normal) but not vertigo, past-pointing or falling, a lesion of the middle cerebellar peduncle is suggested, (2) causes vertigo, past-pointing and falling (all normal), but not nystagmus, a lesion in posterior part of the pons near the medial longitudinal bundle is suggested.*

III. *If stimulation of all the canals of one ear, (1) causes no nystagmus, vertigo, past-pointing or falling, a lesion of the labyrinth or vestibular nerve of that side is indicated, (2) causes nystagmus (normal) but not vertigo, past-pointing or falling, a lesion of the cerebellar nuclei of that side is suggested, (3) causes vertigo past-pointing and falling (all normal), but not nystagmus, it suggests a lesion of the medial longitudinal bundle.*

IV. *If stimulation of all canals of both ears causes nystagmus (normal) but not vertigo, past-pointing or falling, it suggests a lesion in the midbrain at the point of decussation of the superior cerebellar peduncles.*

MÈNIÈRE'S SYNDROME

The features of this condition are paroxysmal attacks of vertigo, noises in the ears (tinnitus) and usually deafness of the inner ear type (p. 1045). Loss of consciousness may occur. There may be spontaneous horizontal nystagmus. The sense organs of the cochlea (organ of Corti) as well as those of the semicircular canals are affected in this

disease, which leads Crowe to believe that a common factor, namely, alterations in pressure of the endolymph or in its chemical composition is the most likely cause of the symptoms. The surgical treatment of the condition consists of severing the vestibular portion of the 8th nerve in the internal auditory meatus, leaving the cochlear division intact (McKenzie; Dandy).

CHAPTER LXVII

THE SPINAL CORD AND BRAIN STEM (MEDULLA, PONS AND MID-BRAIN)

OUTLINE OF THE INTERNAL STRUCTURE OF THE CORD

In figure 361 the spinal cord is shown in cross-section. The *gray matter*, centrally placed, is in the form of an H. It is composed of a mass of nerve cell bodies and nerve fibers (dendrons and axons), mostly unmyelinated, supported by a framework of neuroglia. The ventral and dorsal portions of each lateral half of the gray mass (i.e., each arm of the H) are commonly referred to, respectively, as the ventral (or anterior) and dorsal (or posterior) horns; but since the gray matter extends throughout the length of the cord "column" is a more suitable term than "horn." In the ventral columns are situated the large bodies (100μ in diameter) of the motor neurons whose axons leave the cord by the ventral roots. Each neuron ends in a group of skeletal muscle fibers—the neuromuscular structure constituting the so-called motor unit (p. 816). In the thoracic and upper lumbar segments, the gray mass lying between the ventral and dorsal columns shows a small lateral projection. This constitutes the lateral column or horn; it contains a group of nerve cells (the *intermedio-lateral cell column*) which give rise to sympathetic (efferent) fibers. The well-defined collection of cells occupying the inner part of the base of the posterior horn is known as *Clarke's column*; this group since it is confined almost entirely to the thoracic region of the cord is also known as the *dorsal nucleus*. To the outer side of the base of the posterior column is an area where strands of white matter and prolongations in the main mass of gray matter intermingle to form a delicate interlacement. This is known as the *reticular formation* (*formatio reticularis*) and is found chiefly in the cervical region. It is continuous with the reticular formation of the medulla and pons. At the apex of the dorsal horn is a cap of gelatinous material containing groups of small nerve cells possessing many dendrites named the *substantia gelatinosa of Rolando*. The central part of the cord lies near the center of the bar or nucleus connecting the gray matter of the two lateral halves. The portions of gray matter lying in front and behind the canal are named, respectively the *anterior* and *posterior gray commissures*.

The *white matter* which completely surrounds the gray matter is composed of bundles of myelinated fibers. A deep cleft on the ventral aspect of the cord (the *anterior median fissure*) and a septum upon the dorsal aspect (*posterior median septum*) together, divide the white matter into two lateral halves. Each half is further marked out, by the fibers of the ventral and dorsal nerve roots, into three white columns or funiculi, ventral (anterior), lateral and dorsal (posterior). The *ventral funiculus* lies between the anterior median fissure on the one hand, and the ventral gray column (anterior horn) and the fibers of the ventral roots on the other. Bounded in front and medially by the last two structures, and postero-medially by the dorsal gray column and the fibers of the dorsal roots lies the *lateral funiculus*. The *dorsal funiculus* is situated between the dorsal gray column (posterior horn) and the dorsal root fibers which form its antero-lateral boundary, and the posterior median septum.

THE SPINAL NERVE ROOTS

The *anterior roots* of the spinal nerves are composed entirely of efferent fibers (p. 810).¹ These are (a) the axons of the cells of the anterior horns and (b) in the thoracic and upper lumbar regions, the preganglionic fibers of the sympathetic system already mentioned as arising from the cells of the lateral gray column. The *posterior roots* are constituted of afferent fibers from the skin, muscles and

¹ Although doubt has been expressed from time to time concerning the purely efferent nature of the fibers composing the anterior roots, no substantial evidence has been ever brought forward to show that this is not so. It is true that stimulation of the central end of an anterior root sometimes gives rise to pain, but this is due to the presence of recurrent fibers from the posterior roots and in no way invalidates the Bell-Magendie law. Neurons have been found in the anterior roots resembling those of the posterior root ganglia, but there is no evidence that they are sensory in function. Some authors have been led to believe that the anterior roots transmit sensory impulses because pain is not always relieved by section of the posterior roots. There are three possible reasons for the failure of this operation. In the first place, the pain may arise within the central nervous system itself, a filament of a posterior root may have escaped division, or innervation from adjacent spinal segments may overlap to an unusual extent; pain would then continue to be registered from the area innervated by the severed roots.

viscera. Their cell bodies lie in the spinal ganglia. There is no important evidence that they contain efferent fibers. (See Bell-Magendie law, p. 808 and also p. 236.) Two divisions of the posterior root, a medial and a lateral, are distinguished. The lateral division is largely composed of small unmyelinated fibers; these, after entering the cord form the small triangular area at the tip of the posterior horn known as Lissauer's tract (p. 849). The fibers of the medial division, which are for the most part heavily myelinated, enter the posterior columns of the cord (see fig. 361).

THE SEGMENTAL DISTRIBUTION OF THE SPINAL NERVES

In the young mammalian embryo and in certain adult lower forms, e.g., fishes, the body is demarcated into a regular series of transverse segments or *metameres*. The muscles (*myotomes*), skin (*dermatomes*) and viscera of each of these primitive blocks eventually receive innervation from the nerve roots of a corresponding spinal segment. The anterior root of each spinal nerve supplies motor fibers to the respective myotome, and autonomic fibers to the viscera and skin; the posterior root supplies sensory fibers to the corresponding dermatome as well as to the muscles and viscera. As a result of the outgrowth of the embryonic limbs the orderly arrangement of the metameres from before backwards becomes altered. In the adult mammal, the primitive metameric disposition is observed only in the trunk. The fibers of the spinal nerves supplying the limbs have joined to form the brachial and lumbo-sacral plexuses and, after intermingling freely, issue again as the peripheral nerves. The latter, in consequence, are composed of fibers derived from two or more spinal segments, and fibers from a given segment pass into several peripheral nerves. The muscles supplied by a given spinal segment do not necessarily lie in close proximity to one another (the coracobrachialis, for example, is innervated by the same segments as those which supply the muscles of the thumb) and a single muscle may derive its nerve supply from more than one spinal segment (see page 865). As development proceeds and the limbs grow out from the trunk, the dermatomes become arranged in a series of narrow areas lying for the most part in the long axis of the limb (fig. 357). The skin and muscles of the limbs also tend to move away from the visceral structures with which they were originally associated and, in the adult, innervated

originally associated and, in the adult, structures innervated by a common spinal segment may widely separated. Thus, the diaphragm is innervated (through the phrenic) from the 3, 4 and 5 cervical segments which also supply skin and muscle in the region of the neck and shoulder. The heart receives sensory and autonomic fibers from the upper thoracic segments; these segments also supply sensory fibers to the skin over the

FIG. 357. Showing the drawing out of the metameres of the embryo with the development of the limb-bud (redrawn and modified from Gray, *Anatomy of the Human Body*).

aspect of the arm and hand and upper part of the thorax. The distribution of the dermatomes and cutaneous nerves in the human subject are shown in figures 358 and 359.

Several methods have been employed by different investigators in mapping out the dermatomes in animals and in the human subject. The *anatomical* method is laborious and consists in tracing the fibers of a spinal root to their termination in the skin. A *physiological* method ("isolation" or "sensory remainder" method) was employed by Sherrington in cats and monkeys. The area of skin supplied by a given segment was demarcated by dividing the sensory roots above and below. The sensitive area of skin bounded above and below by an anesthetic zone indicated the distribution of the undivided roots. Owing

overlap of fibers from adjacent segments, it is not possible to produce an anesthetic area by the division of the sensory roots of a single segment (fig. 360). Head mapped out the segmental distribution of the cutaneous nerves in the human subject from studies of cases of herpes zoster, a condition due to a lesion of the ganglion cells of the

—from higher centers to spinal neurons. (b) *short tracts* (intersegmental or association tracts, ground bundles) which begin and end within the cord and connect different spinal segments. The fiber tracts making up the substance of the respective funiculi are listed in table 78 and shown diagrammatically in figure 361.

FIG. 358. The two figures to the right represent Head's cutaneous areas, as displayed in his original papers. Small areas of C5 and C6, coinciding with T1 and T3 on the back, have been omitted. The left-hand figure has been constructed from Foerster's data (49) and represents his "dermatomes". (after Lewis)

posterior roots. Within more recent years Foerster, using Sherrington's method has mapped out the dermatomes in man. He also stimulated the posterior roots at operation and used the resulting vascular reaction (vasodilatation) as the means of demarcating the dermatomes.

THE TRACTS OF THE CORD

The fiber tracts of the cord are divisible into two main groups: (a) *long tracts* (projection tracts) which connect the cord with other parts of the central nervous system. Some of these (ascending tracts) carry impulses to higher centers; other tracts (descending) conduct in the reverse direction

ASCENDING TRACTS OF THE CORD

(1) **THE DORSILATERAL FASCICULUS (TRACT OF LISSAUER).** This is seen in cross section as a small area lying between the tip of the posterior horn and the periphery of the cord (fig. 361). It is composed of fibers derived from the lateral division of the posterior nerve roots. These fibers upon entering the cord form synapses immediately, or after a very short upward course, with cells occupying the tip of the posterior horn, i.e., in the substantia gelatinosa of Rolando (p. 847). The fibers of this tract are mostly of small diameter and unmyelinated, and are believed to constitute the primary neurons in the pathway for pain and

crude thermal sensations. The axons of the secondary neurons go to form the lateral spinothalamic tract, to be immediately described

in the posterior funiculus for a variable number of segments before entering the gray matter crossing to the ventral spinothalamic tract

FIG. 359. Showing distribution of cutaneous nerves; anterior aspect of body on left, posterior on right. I, iliohypogastric and genitofemoral nerves; L, ilio-inguinal nerve; P-C, on left side, P, on right side, posterior cutaneous nerve of thigh; O, obturator nerve; H, iliohypogastric nerve; L, posterior branches of 1st, 2nd lumbar nerves; S, posterior branches of 1st, 2nd and 3rd sacral nerves.

(2) THE LATERAL (POSTERIOR) AND VENTRAL (ANTERIOR) SPINOTHALAMIC TRACTS. The fibers of the lateral tract arise, as mentioned above, from cells in the substantia gelatinosa of Rolando; those of the ventral tract arise from cells in the adjacent gray substance of the posterior horn. The fibers constituting these tracts, after crossing the mid-line in the anterior gray commissure, ascend respectively in the lateral and ventral white columns of the cord. The ventral spinothalamic tract is a crossed pathway for the mediation of touch, light pressure and localization (p. 853). The lateral spinothalamic tract transmits impulses aroused by all forms of thermal and painful stimuli applied to the opposite side of the body. The primary neurons in the pathway for tactile sensations after entering the cord ascend

FIG. 360. Diagram showing the overlap of skin area innervated through the fourth thoracic nerve root by those supplied by the third thoracic nerve root. The small circle indicates the position of the nerve root (after Sherrington).

opposite side. As mentioned above, the neurons of the pathway for thermal and painful sensations enter the gray matter almost immediately and cross to the opposite side. The tracts come together in the medulla and ascend on the outer side of the medial lemniscus

teroventral nucleus of the thalamus (see 879).

THE SPINOTECTAL TRACT is placed in the column ventral to the lateral spinothalamic. Its fibers arise from cells in the posterior of the opposite side and terminate in the inferior colliculus. It subserves spinovisual reflexes.

SPINOCEREBELLAR TRACTS. (a) The *dorsal cerebellar tract* (direct cerebellar or tract of Goll) is situated in the posterior part of the funiculus to the outer side of the lateral spinothalamic tract. It is composed of the axons of the cells of Clarke's column (p. 847) of the opposite side. The direct cerebellar tract reaches the cerebellum via the inferior cerebellar peduncle; its fibers end mainly in the cortex of the anterior and posterior lobes of the cerebellum (p. 923). (b) The *ventral spinocerebellar tract* (indirect cerebellar or tract of Burdach) arises from the cells of Clarke's column, of the same, but also of the opposite side of the cord. It ascends in front of the dorsal cerebellar tract and is continued upwards through the brain stem as far as the mid-brain where it arches backwards and downwards (arcuate fibers) to reach the cerebellum via its superior peduncle. Its constituent fibers end in the cortex of the anterior and posterior cerebellar lobes. Spinocerebellar tracts carry impulses arising from proprioceptors of the muscles, tendons and joints. The information thus conveyed to the cerebellum is essential for the latter's function in regulating the tone of the skeletal muscles and coordinating their movements (p. 928).

THE FASCICULI GRACILIS (TRACT OF GOLL) AND THE FASCICULUS CUNEATUS (TRACT OF BURDACH) occupy the posterior funiculus of the cord, the former being medial to the latter. These tracts are composed of the heavily myelinated fibers of the posterior division of the homolateral posterior nerve roots. Which, after their entrance into the cord, divide into long ascending and short descending tracts. The latter after a short course enter the anterior horn (see fasciculus interfasicularis, p. 879). The former, as they proceed upwards, are displaced medially, with the result that those arising at lower levels (e.g., sacral region) lie closer to the midline than those entering at higher levels (e.g., cervical region). Consequently, the posterior division of the cord in the mid-dorsal region upwards the more medially placed tract (fasciculus gracilis) is composed of fibers derived from the lower thoracic, lumbar and sacral nerve roots, whereas the fasciculus cuneatus is constituted of fibers derived from

the upper thoracic and cervical nerve roots. Of the constituent fibers of the two tracts, some, after ascending for a variable number of spinal segments end in the gray matter of the cord and cross to the opposite side and ascend as the anterior spinothalamic tract. The remaining fibers of the fasciculi gracilis and cuneatus proceed uncrossed to end, respectively, in the nucleus gracilis and nucleus cuneatus situated in the lower part of the medulla. From these nuclei the axons of secondary neurons emerge and, passing medially as the *internal arcuate fibers*, decussate with those of the opposite side (sensory decussation). They ascend through the brain stem as the *medial lemniscus* (p. 854) to terminate in the lateral nucleus of the thalamus. Other fibers (*external arcuate*) from the nuclei gracilis and cuneatus relay to the cerebellum (p. 924) non-sensory impulses brought to them by the corresponding spinal fasciculi.

Summary of the principal pathways ascending through the cord

A. SENSORY. (1) The fibers mediating thermal and painful sensations enter the cord in the lateral divisions of the posterior nerve roots. According to Ranson they are unmyelinated. Within the cord they constitute Lissauer's tract. Immediately, or after a very short upward course, they enter the posterior gray column and connect with nerve cells therein. The axons of these secondary neurons cross to the opposite side in the anterior gray and the anterior white commissures and ascend as the lateral spinothalamic tract. This tract occupies a position in the brain stem lateral to the medial lemniscus and ends in the lateral nucleus of the thalamus (cf. figs. 361 and 362).

(2) The fibers conveying all other sensory impulses, e.g., from the muscles and joints (sense of movement and position), impulses for touch, pressure, tactile localization and spatial discrimination (compass test), enter the cord in the medial division of the posterior roots and ascend in the fasciculus gracilis and fasciculus cuneatus. (a) Those mediating the sense of movement and position of the limbs and spatial discrimination do not cross in the cord but pass directly to the nucleus gracilis and nucleus cuneatus where they connect with secondary neurons. The axons of the latter decussate with those of the opposite side and ascend to the thalamus as the medial lemniscus (or fillet). Tertiary neurons convey the impulses to the cerebral cortex. (b) Fibers conveying impulses

FIG. 361. Diagram to show tracts of the cord. Ascending fibers shown in blue, descending in red, spinal motoneuron in black. 1, represents fibers ascending in posterior columns (mediating sensations of touch, spatial discrimination, and of position and movement); 2 and 10, represent fibers entering the contralateral and homolateral ventral spinothalamic tracts, respectively; 3, represents fibers entering dorsal spinothalamic tract of the opposite side (mediating pain and thermal sensations); 4, represents fibers entering ventral spinothalamic tract of the opposite side (mediating touch and tactile localization); 5, fiber entering dorsal spinothalamic tract; 6, internuncial neuron connecting a posterior root fiber with anterior horn cell (reflex arc); 7 and 8, crossed corticospinal fibers connecting, respectively, through an internuncial neuron and directly, with anterior horn cell; fiber of an

for *light touch*, *light pressure* and *localization* ascend for variable distances in the dorsal fasciculi but the majority eventually connect with cells in the dorsal gray column; the axons of these cells cross

even pass uncrossed to the nuclei gracilis and cuneatus. The result is that these sensations have virtually two pathways in the cord. Therefore, in a lesion involving the dorsal fasciculi, touch,

FIG. 362. Diagram showing the course of afferent impulses after their entrance into the cord. *Red*, pathway for pain and thermal sensations (ascend in dorsal spinothalamic tract of opposite side). *Blue*, pathway for touch, sense of position and movement, and spatial discrimination (ascend in posterior columns); external arcuate fibers from posterior column nuclei to cerebellum also shown. *Green*, pathway for touch, and tactile localization (after travelling for variable distances in posterior columns, fibers cross to ventral spinothalamic tract of opposite side). *Black*, ventral and dorsal spinocerebellar tracts, some fibers of latter (not shown) also cross to opposite side.

in the anterior gray commissure and ascend in the ventral (anterior) spinothalamic tract. It appears from clinical observation that of the fibers mediating these sensations from a given region of the body some cross after a short upward course, others after a much longer course, and some may

pressure and tactile localization are little affected since they are still capable of being conveyed by fibers which have already crossed (i.e., below the lesion) to the ventral spinothalamic tract (see also hemisection of the cord). Impulses subserving light touch and tactile localization, but not

the cruder sensation of skin pressure, are relayed from the thalamus to the cerebral cortex.

B. NON-SENSORY. Non-sensory impulses from the muscles, tendons and joints are conveyed into the cord by fibers composing the medial divisions of the posterior roots. These fibers connect immediately with the cells of Clarke's column and are continued upwards in the dorsal (direct) and ventral (indirect) cerebellar tracts of the same side, mainly, but also of the opposite side. Some of these non-sensory impulses are conveyed by fibers of the posterior fasciculi to the nuclei gracilis and cuneatus from where they are relayed by secondary neurons (external arcuate fibers) via the inferior peduncles to the cerebellum. (See fig. 362.)

THE REGROUPING OF AFFERENT IMPULSES IN THE CORD. It will be noted that in the cord the fibers mediating the several types of sensation are grouped without regard to the three peripheral systems, protopathic, epicritic and deep sensibility (p. 803). A regrouping occurs in which fibers conveying impulses for spatial discrimination belonging to the epicritic system ascend with those for muscle sense (deep sensibility) in the dorsal fasciculi. Those fibers mediating touch, light pressure and localization ultimately ascend together in the ventral spinothalamic tract while temperature and pain are segregated in the lateral spinothalamic tract. In the thalamus the impulses undergo a second resorting; the paths for crude sensations, e.g., of pain and of the extremes of temperature do not ascend beyond this level (p. 880). The other more discriminative qualities of sensation are continued upwards to the cerebral cortex.

SENSORY PATHS IN THE BRAIN STEM (MEDULLA, PONS AND MID-BRAIN)

The *medial lemniscus* (or fillet). This is constituted of fibers arising in the nuclei gracilis and cuneatus, that is, of the axons of secondary neurons in the pathway mediating spatial discrimination and muscle sense. The fibers leave the ventral aspects of these nuclei and arch forward and medially (as *internal arcuate fibers*) to the mid-line where they cross with corresponding fibers of the opposite side (*sensory decussation*). They then turn upwards as a compact bundle known as the medial lemniscus or fillet. This ascends through the medulla and pons dorsal to the pyramidal tracts, and through the tegmentum of the mid-brain.

The *spinal lemniscus* (or fillet) is formed by the fusion of the anterior and lateral spinothalamic

tracts and is therefore a crossed path for impulse aroused by light touch, pressure, pain, heat and cold.

The *trigeminal lemniscus* (or fillet) conveys impulses from the area of distribution of the trigeminal nerve of the opposite side (p. 857).

The fibers of the medial, spinal and trigeminal lemnisci terminate in the nucleus of the thalamus, from where tertiary neurons pass to the cerebral cortex (p. 893).

The *lateral lemniscus* constitutes the pathway for auditory impulses from the cochlear nucleus and superior olive to the inferior colliculus and medial geniculate body (p. 1024).

The sensory pathways are constituted of three neurons. The path for spatial discrimination and muscle sense, for example, consists of a primary neuron whose cell body lies in the posterior root ganglion, a secondary neuron originating in the posterior column nucleus (gracilis or cuneatus) and a tertiary neuron arising in the lateral nucleus of the thalamus. The cells of the Gasserian ganglia are the primary neurons of the trigeminal pathway; secondary neurons lie in the sensory nucleus and in the spinal nucleus of the nerve (p. 858). The spinal lemniscus is composed of the axons of secondary neurons whose cell bodies lie in the posterior gray columns of the cord; the primary neurons arise in the posterior root ganglia.

In the upper part of the medulla the medial lemniscus is joined on its outer side by the spinal lemniscus. In the pons the fibers of the contralateral sensory nucleus of the trigeminal join the medial fillet, and fibers from the opposite spinal nucleus of the trigeminal join the spinal lemniscus. In the upper part of the pons and in the mid-brain these several sensory pathways become fused together into a compact bundle. A lesion in the lower part of the brain stem may involve one of the sensory pathways exclusively of the others. Thus an injury localized to the outer part of the lower pons or of the medulla may by injuring the spinal lemniscus cause loss of sensation to pain, heat and cold over the *opposite half* of the body, leaving muscle sense and tactile discrimination intact. Sensory loss of this nature accompanied by cerebellar symptoms occurs as a result of the occlusion (as by thrombosis or embolism) of the posterior inferior cerebellar artery. Usually also as a result of the involvement of the spinal tract of the trigeminal nerve (p. 858) the face on the *same side* as the occluded vessel shows the dissociated sensory loss. A lesion more centrally placed may, by implicating the medial fillet alone, cause

the converse type of dissociated sensory defect, namely, loss of the sense of position of the limbs and of spatial discrimination with retention of sensibility to pain, heat and cold. In lesions at higher levels in the brain stem all forms

Sheehan a tract of uncrossed pyramidal fibers in the lateral column of the cord. Through these two tracts (anterior and lateral) of uncrossed fibers the skeletal muscles of each side of the body receive impulses from both motor areas of the cortex.

sensation are likely to be involved more or less equally.

DESCENDING TRACTS OF THE CORD

(1) THE CORTICOSPINAL OR PYRAMIDAL TRACTS. The origin of the corticospinal tracts and their course through the cerebrum and brain stem are described on page 862. The tract of each side divides into two bundles at the lower border of the medulla. The larger of these crosses with the corresponding bundle of the opposite side and descends in the posterior part of the lateral funiculus of the cord as the *lateral corticospinal tract* (crossed pyramidal tract). The remaining fibers, uncrossed, descend in the anterior funiculus as the *anterior corticospinal tract* (direct pyramidal tract). The direct pyramidal tract is well marked in the cervical region but its fibers dwindle gradually in number, in successive segments. They may be traced, however, as far as the sacral region; a proportion of the fibers of this tract also cross eventually to the opposite side of the cord, passing at different levels through the anterior commissure. (Cf. figs. 361 and 363.) Besides the well-recognized anterior (direct) corticospinal tract there is, shown by Schafer and lately by Fulton and

The corticospinal fibers (crossed and uncrossed) connect with the large motor cells of the ventral gray columns (anterior horn cells). The connections are of two types, (a) direct synapses with the motor neurons, (b) indirect connections with these cells through an internuncial neuron whose cell body is also in communication with a posterior root fiber on each side (fig. 363).

(2) THE VESTIBULOSPINAL TRACTS. These are two in number; a ventral and a lateral. The *ventral vestibulospinal tract* descends in the forepart of the anterior funiculus and lateral to the anterior portion of the direct pyramidal tract. Its fibers arise from the lateral vestibular nucleus (Deiter's) chiefly of the same side, and may be traced as far as the sacral region. The fibers terminate by forming synapses with the motor neurons either directly or through an internuncial neuron. The *lateral vestibulospinal tract* is smaller. Its fibers—the axons of cells in Deiter's nucleus—descend in the lateral column of the same side. The vestibulospinal tracts form a section of the pathway from the labyrinth and the cerebellum to the skeletal muscles.

(3) THE TECTOSPINAL TRACT is composed of fibers which arise in the superior colliculus of the

opposite side and descend through the reticular formation of the pons and medulla. Upon entering the cord the tract separates into a ventral and a dorsal bundle which descend in the corresponding spinal funiculi. The fibers of this tract synapse with the motor neurons either directly or through internuncial neurons. The superior colliculus receives nerve impulses from the retina and through its connections with the spinal motor

Here the rubrospinal fibers connect either directly or through internuncial neurons with the motor neurons, to which they relay impulses from the cerebellum and striate body.

(5) THE OLIVOSPINAL (BULBOSPINAL) TRACT OF HELWEG. Its fibers arise from cells in the neighborhood of the olivary nucleus and descend in the ventral part of the lateral funiculus. They descend no farther than the cervical region. The

FIG. 363. Diagram showing pyramidal tracts (black), rubrospinal tracts (red), tectospinal tracts (blue) and vestibulospinal tracts (green). B.C., Betz cell of motor cortex; R.N., red nucleus; S.C., superior colliculus; V.N., vestibular nucleus.

neurons visual impulses are correlated with body movements (visuospinal reflexes).

(4) The RUBROSPINAL TRACT arises from the large cells (nucleus magnocellularis) in the posterior part of the red nucleus (p 874). The fibers immediately upon leaving the red nucleus cross to the opposite side (*Forel's decussation*) and descend through the reticular formation of the pons and medulla to enter the lateral funiculus of the cord ventral to the lateral corticospinal tract.

The fibers synapse with the motor neurons. The functions of this tract are unknown. It and the thalamo-olivary tract constitute a possible pathway whereby impulses from the thalamus may reach the spinal centers.

(6) The RETICULOSPINAL TRACTS arise from cells scattered through the reticular formation of the upper part of the pons. They are two in number, one (uncrossed) descends in the anterior funiculus and the other (crossed) in the lateral funiculus. The

THE NERVOUS SYSTEM

connect with the motor neurons in the anterior horns and probably with cells in the lateral horn. These tracts transmit impulses from the striate body and cerebellum.

INTERSEGMENTAL TRACTS OF THE CORD AND THE MEDIAL LONGITUDINAL FASCICULUS

There is in each funiculus of the cord lying close to the gray matter an intersegmental fasciculus or ground bundle. These, as already mentioned, serve to link up spinal segments of different levels. Their fibers arise from cells in the gray matter and after an ascending or descending course of variable length end around cells of the same or the opposite side at a higher or a lower level. The proportion of the fibers constituting the intersegmental fasciculus of the lateral column of the cord (*lateral intersegmental fasciculus* or *lateral ground bundle*) are continued upwards into the medial longitudinal fasciculus of the brain stem. The ground bundle of the anterior funiculus (*anterior intersegmental fasciculus* or *anterior ground bundle*) is composed of fibers which connect the anterior horn cells of one side with those of the opposite side both at the same and at different levels. Some of the fibers also pass upwards into the medial longitudinal fasciculus.

The posterior funiculus contains (a) the septo-marginal fasciculus and (b) the posterior intersegmental fasciculus (or posterior ground bundle).

The *septo-marginal fasciculus* is composed of intersegmental fibers which arise from cells of the posterior horn and synapse with corresponding cells at lower levels. The descending fibers of the medial divisions of the posterior nerve roots (p. 847) also enter into the constitution of this tract. The fibers of the septo-marginal fasciculus occupy different positions at different spinal levels. In the cervical and upper thoracic regions the fibers appear on section as a crescentic area at about the center of the posterior funiculus. Here they are spoken of as the *common tract* or *tractus interfascicularis*. In the lower thoracic region they form a narrow zone bounding the posterior part of the cord and known as the *dorsal peripheral band*. In the lumbar region they appear on section as a semi-oval mass—the *oval area of Flechsig*—abutting against the posterior median septum.

The *posterior intersegmental fasciculus* is seen in cross section as a small area lying behind the posterior gray commissure. Its fibers connect the posterior horn cells of different segments (see fig. 361).

THE MEDIAL LONGITUDINAL FASCICULUS

The medial (posterior) longitudinal fasciculus (bundle) is a compact tract composed of short

ascending and descending fibers which connect the nuclei of the cranial nerves with each other (fig. 353). It is homologous with the anterior intersegmental fasciculus of the spinal cord. The tract lies near the mid-line and extends from the upper segments of the cord to the floor of the 3rd ventricle. In the medulla it lies immediately subjacent to the floor of the 4th ventricle; in the pons it courses through the *formatio reticularis*, and in the mid-brain, lies in the floor of the Sylvian (cerebral) aqueduct. It is continuous below with the ground bundles of the anterior and lateral funiculi of the spinal cord. The fasciculus receives many fibers from the vestibular nuclei (p. 836) of the same and of the opposite side, from the lateral lemniscus (auditory path, p. 1024) and from the superior colliculus, through which it is in communication with the optic pathway (p. 1009). It sends fibers to the nuclei of the oculomotor, trochlear, abducens, facial, accessory and hypoglossal nerves. Its essential function is the coordination reflex movements of the ocular and neck muscles in response to labyrinthine, auditory and visual stimuli.

THE CENTRAL CONNECTIONS OF THE TRIGEMINAL, FACIAL, GLOSSOPHARYNGEAL, VAGUS, ACCESSORY AND HYPOGLOSSAL NERVES

The trigeminal pathway

The trigeminal nerve appears near the upper border of the ventral surface of the pons and consists of three roots (a) a large *sensory*, (b) a small *motor*, and (c) a *mesencephalic* (fig. 364).

The fibers of the *sensory root* convey impulses from the anterior part of the scalp, from the skin of the forehead and face, with the exception of an area over the angle of the mandible, and from the upper half or so of the pinna. It also supplies the mucous membrane of the mouth (anterior two-thirds of tongue) and nose; and the cornea and conjunctivae. This root arises from the cells of the Gasserian (semilunar) ganglion. The processes of these cells divide into peripheral and central branches. The former enter into the composition of the peripheral divisions (ophthalmic, maxillary and mandibular) of the nerve; the central branches (which constitute the sensory root) enter the pons in close association with the fibers of the motor root and divide into an ascending and a descending group. (a) The *ascending fibers* convey impulses of light touch, tactile discrimination and localization, and of the sense of position and passive movement. They end in a

nucleus (*upper sensory nucleus of the trigeminal*) situated in the pons, deep and lateral to the motor nucleus. (b) The *descending fibers* constitute the *bulbospinal tract of the trigeminal*. They subserve sensations of pain and temperature over the entire trigeminal area. They descend through the pons and medulla and may be traced as far as the 2nd cervical segment. This tract dwindles gradually in its descent, its fibers terminating around cells in a mass of gray matter in relation to it. This collection of gray matter is known as the *spinal nucleus of the trigeminal*. The fibers of the mandibular, maxillary and ophthalmic divisions of the trigeminal end in the nucleus in this order

FIG. 364. Diagram of the central connections of the trigeminal nerve.

from above downwards, that is, in an order the inverse of that in which they are distributed to the skin of the face. From the spinal nucleus the axons of secondary neurons emerge which cross the mid-line; ascending, they join fibers arising from the upper sensory nucleus to form the trigeminal lemniscus (or fillet). The trigeminal lemniscus lies in close association with the spinothalamic tracts and medial lemniscus (p. 854); its fibers terminate in the posteroventral nucleus of the thalamus.

The upper sensory nucleus of the trigeminal corresponds to the nuclei of the posterior columns of the cord (nuclei gracilis and cuneatus) and like the latter sends fibers to the cerebellum through the inferior cerebellar peduncle. The spinal tract of the trigeminal may be looked upon as corresponding to the tract of Lissauer (p. 849), and the spinal nucleus as an extension upwards of the substantia gelatinosa of Rolando

whose cells, as we have seen, give rise to the late spino-thalamic tract.

The *motor root* fibers arise from a nucleus in the upper part of the pons underlying the lateral wall of the floor of the 4th ventricle. The nucleus receives fibers from the corticobulbar tract of the opposite side and also probably from the same side. The motor root after its emergence from the brain travels peripherally with the sensory root and, passing deep to the Gasserian ganglion, joins the mandibular (3rd) division of the trigeminal nerve to supply the muscles of mastication (temporalis masseter and pterygoids).

The *mesencephalic root* consists of a small bundle of fibers which run in company with the fillet of the motor root. Entering the pons they ascend to the *mesencephalic nucleus* of the trigeminal, an elongated mass of gray matter extending from the level of the motor nucleus to the upper region of the mid-brain. It was thought at one time that the mesencephalic root and nucleus were motor in function, but it is now generally admitted that they are composed of afferent neurons. The nucleus is looked upon as a group of cells homologous with the Gasserian ganglion and the posterior root ganglia of the spinal nerves, but which have migrated into the brain at a very early period of phylogenetic development. It is believed by Kappers to receive proprioceptive impulses from the muscles of mastication.

LESIONS INVOLVING THE TRIGEMINAL PATHWAYS. Either the peripheral portions or the central connections of the nerve may be the seat of disease. A lesion of the nerve peripheral to the Gasserian ganglion is more likely to involve only one or two of the three divisions. Pain, loss of sensibility or parosmia, or even eruptive eruptions, over the distribution of the divisions affected, may result. Paralysis of the muscles of mastication may follow injury or disease of the mandibular division, or analgesia of the cornea with ulceration (neuropathic keratitis) may result from an affection of the ophthalmic division. Loss of sensation of taste (as well as of ordinary sensibility) over the anterior two-thirds of the tongue on the corresponding side is a common accompaniment of degenerative changes affecting the mandibular division of the 5th nerve. The taste fibers to this part of the tongue are derived from the chorda tympani branch of the facial, which travel via the lingual branch of the mandibular division of the trigeminal. The loss of taste is due to pressure upon the chorda fibers by the degenerating lingual filaments, and is, as a rule, only

ary. Taste fibers are not constituents of the nerve itself. Removal of the Gasserian ganglion, for instance, does not result in permanent loss of taste on the operated side. Degeneration of the nerve central to the ganglion may occur in cases. Lesions (e.g., tumors, vascular changes) of the pons, medulla or upper cervical cord may involve the upper sensory nucleus, the motor nucleus, the trigeminal fillet (crossed) or the bulbospinal tract of the nerve. When the motor nucleus is involved weakness of the muscles of mastication results; implication of the ascending sensory fibers, or of the main sensory nucleus in the pons, is followed by loss of the sensation of touch and the discriminative aspects of cutaneous sensibility over the same side of the face, but the retention of sensibility to pain, heat and cold. The neighboring spinothalamic tract (crossed) may suffer coincidentally with the ascending sensory fibers, when thermanesthesia and analgesia over the trunk and limbs of the opposite side combined with loss of tactile sensation over the face of the same side will result (see also p. 209). Syringomyelia extending into the upper cervical region or into the bulb (syringobulbia) is likely to cause, as a result of pressure upon the spinal tract of the nerve, dissociated sensory loss of the reverse character (loss of pain and temperature and retention of tactile sensibility). Through its central connections with other cranial nerves the afferent fibers of the trigeminal nerve mediate several reflex acts, e.g., sneezing, through its nasal branches and the connections of the sensory nucleus with the nucleus of the vagus, the oculo-cardiac reflex (p. 209) through its ophthalmic fibers and the vagus, and the winking and corneal reflexes through the ophthalmic division of the facial nerve.

The trigeminal nerve, or one of its divisions, is sometimes the seat of a severe and intractable form of pain which recurs in paroxysms (*trigeminal neuralgia*) and may be accompanied by reflex spasms of the facial muscles (*tic douloureux*). The cause of the affection is unknown. In treating the condition, injections of alcohol into the division of the nerve involved are sometimes employed. An injection is made into the nerve at the infra-orbital foramen or foramen rotundum in the case of involvement of the maxillary division, and at the foramen ovale of the sphenoid or at the supraorbital notch, respectively, in disease of the mandibular division. Injections into the ganglion itself, or section of the sensory root before it enters the ganglion, is more likely to be followed

by permanent relief. The attempt is frequently made to sever the fibers entering into the constitution of the maxillary and mandibular divisions only, leaving those of the ophthalmic division, which is rarely affected, intact. The object of sparing the latter division is to obviate the corneal lesions which may result from degeneration of its fibers. The greater proportion of the fibers of the former two divisions are segregated upon the under aspect of the sensory root.

The facial nerve

The facial nerve consists of a large *motor* and a small *sensory* portion. The two portions or roots appear at the lower border of the pons and enter the internal auditory meatus in company with the auditory nerve.

The *sensory portion* of the facial, which is also known as the *nervus intermedius of Wrisberg*, contains not only afferent fibers but secretory and vasodilator (parasympathetic) fibers as well. The sensory fibers arise from the cells of the genicular (geniculate) ganglion (fig. 365). The peripheral processes of these cells are distributed through the chorda tympani branch of the facial nerve to the taste buds and mucous membrane of the anterior two-thirds of the tongue, and through the great superficial petrosal nerve and the sphenopalatine ganglion to the mucosa of the soft palate and posterior part of the nose. The chorda tympani branch joins the trunk of the lingual nerve through which it is conveyed to the floor of the mouth.² Deep sensibility (pressure pain) from the facial muscles is also, according to Loyal Davis, conveyed by afferent fibers which are distributed with the motor fibers but pass centrally in the *nervus intermedius*. The central processes of the ganglion cells end in the *sensory nucleus* situated in the upper part of the tractus solitarius. Fibers arise from the latter and ascend in the medial fillet of the opposite side to reach the thalamus (anterior nucleus). From here the pathway for taste impulses is continued by tertiary neurons to the

² The *nervus intermedius*, the genicular ganglion, the chorda tympani and part of the great superficial petrosal nerve are sometimes grouped together under the name *glossopalatine nerve*. The origin and distribution of the secretory and sensory fibers of which this nerve is composed are closely similar to those of the glossopharyngeal, and it is considered by some as an aberrant part of the latter nerve.

A small proportion of taste fibers may take an alternative route, namely, via the chorda tympani to the otic ganglion and thence by way of the internal sphenoidal and great superficial petrosal nerves, genicular ganglion and *nervus intermedius* to the brain stem (Schwartz and Weddell).

cortex of the hippocampal gyrus in the region of the uncus.

The *parasympathetic fibers* arise from the *superior salivary nucleus* (p. 942) which lies in close relation to the motor nucleus of the facial. Secretory and vasodilator fibers pass via the great superficial petrosal nerve to the sphenopalatine ganglion from where they are relayed to the lacrymal gland, and to the vessels and glands of the palate and posterior part of the nose. The secretory and vasodilator fibers to the submaxillary and sublingual glands leave the facial with the taste fibers in the chorda tympani branch.

The *motor part* of the facial is conveyed through the facial canal of the temporal bone to the stylomastoid foramen. After its emergence from the latter it is distributed to muscles of the face, auricle, and forehead. The motor fibers arise from a nucleus in the lower part of the pons and pass backwards to the lower end of the nucleus of the abducent nerve. They then ascend behind this nucleus and arching over it pass downwards and forwards to their point of emergence from the brain. As the fibers pass upwards behind the abducent nucleus they form a prominence in the floor of the 4th ventricle, known as the *facial colliculus*.

Connections; the motor nucleus of the facial nerve receives:

(a) Fibers from the cortico-bulbar tract of the same and of the opposite side.

(b) Fibers from the lateral, trigeminal and medial lemnisci, and from the spinothalamic tracts. Through these connections reflex facial movements in animals may be initiated from various receptive areas of the body.

FACIAL PARALYSIS. The effects of interruption of the facial pathway vary in certain important features according to the level at which the injury occurs. The nature of the motor loss following a lesion of the supranuclear fibers is described on page 863. In the paralysis resulting from injury to the trunk of the facial nerve all the muscles of the affected side of the face are completely paralyzed. The subject is unable to close the eye owing to paralysis of the orbicularis oculi, or to frown; the eyebrow droops. The mouth is drawn over to the sound side by the unparalyzed muscles and, unlike the paralysis in hemiplegia, the muscles of the affected side do not take part in the facial expression of emotional states, e.g., laughing or crying.

Facial paralysis may result from a lesion involving:

(a) The motor nucleus or the intra-pontine course of the motor fibers (tumors, hemorrhage, etc.).

(b) The nerve as it crosses the posterior fossa of the skull to reach the internal auditory meatus, as in fractures of the skull or tumors in this situation; the sensory portion and the auditory nerve are commonly involved as well, when loss of the sensation of taste over the anterior two-thirds of the tongue, and deafness on the affected side will result.

(c) The nerve in its course through the temporal bone as in fracture of the skull or in otitis media; inflammation of the nerve within the facial canal (aqueduct of Fallopius)—*Bell's palsy*—may occur.

(d) The nerve after its emergence from the stylomastoid foramen, as it lies behind the angle of the jaw; inflammation, parotid tumors, or accidental injury may implicate the nerve in this situation.

The glossopharyngeal nerve

The glossopharyngeal nerve contains motor, secretory, vasodilator and sensory fibers. The nerve emerges in three or four filaments from the side of the upper part of the medulla in the groove between the olive and the restiform body. The motor fibers are distributed entirely to the stylopharyngeus muscle. The secretory and vasodilator fibers (via its tympanic branch, the great superficial petrosal nerve and the otic ganglion (p. 942) supply the parotid gland. The sensory fibers arise from cells in the jugular (superior) and petrous (inferior) ganglia. The peripheral processes of the ganglion cells supply the taste buds of the posterior third of the tongue and the mucosa of the pharynx and posterior part of the mouth. The central processes terminate in the dorsal nucleus of the vagus and in the lower part of the *tractus solitarius*. Fibers (secondary neurons) pass from the latter nucleus and, crossing to the medial fillet of the opposite side, ascend to the thalamus, from where axons of tertiary neurons pass to the cortex of the hippocampal gyrus. The motor fibers arise from the upper part of the *nucleus ambiguus* situated in the reticular formation of the medulla. Secretory fibers are the axons of cells lying in the *inferior salivary nucleus* which lies below the superior nucleus of the same nerve.

The vagus nerve

The vagus nerve contains motor, secretory, vasodilator and sensory fibers. The secretory and vasodilator fibers are the fibers to the involuntary muscle of the bronchi, heart, esophagus, stomach,

small intestine, gall-bladder, etc. (parasympathetic fibers, p. 942) arise from cells in the *dorsal nucleus* (principal autonomic nucleus). This gray mass extends upwards from the lower, closed part of the medulla to beneath the floor of the 4th ventricle at the level of the striae medullares. The voluntary motor fibers arise in close relationship with the motor fibers of the glosso-

geus), and to most of the muscles of the soft palate and larynx. The cell bodies of the *sensory fibers* lie in the jugular ganglion (ganglion of the root) and ganglion nodosum (ganglion of the trunk). The peripheral processes of these cells convey impulses from the lungs, heart, larynx, pharynx, esophagus, stomach, small intestine and gall-bladder. They also innervate the taste buds

FIG. 365. Diagram to show the central connections of the facial, glossopharyngeal and vagus nerves, and the course of the secretory fibers to the salivary and lacrymal glands. Efferent paths, black; afferent paths, red. T.P., tympanic plexus; T.N., tympanic nerve. Taste fibers to the tongue are conveyed in the chorda tympani and glossopharyngeal nerves, but a small area in the region of the epiglottis receives taste fibers through the vagus. The petrous (inferior) ganglion of the glossopharyngeal and the ganglion nodosum of the vagus are not shown in the diagram.) Erratum; *ambiguous* should be *ambiguus*.

pharyngeal, namely, from the cells of the *nucleus ambiguus* lying below the glossopharyngeal neurons. They supply (through the superior pharyngeal branch) the cricothyroid and arytenoid muscles of the larynx, and the inferior constrictor of the pharynx. The pharyngeal and recurrent pharyngeal branches of the vagus also convey voluntary motor fibers derived from the bulbar nucleus of the accessory nerve (see below) to the pharyngeal muscles (with the exception of the stylopharyn-

of the epiglottis and valleculae (the depressions lying at the sides of the fold running from the epiglottis to the base of the tongue). The taste fibers terminate centrally around cells in the lower extremity of the tractus solitarius. These impulses are relayed upwards along the same paths as those conveying other taste impulses. Afferent vagal fibers from all other structures terminate in the dorsal nucleus. This latter is, therefore, both motor and sensory in function and constitutes an

important visceral reflex center. It contains the cardio-inhibitory and vomiting centers.

The accessory nerve

The accessory (spinal accessory) nerve is entirely motor and is made up of a bulbar and a spinal part. The *bulbar part* arises from the lower end of the nucleus ambiguus from cells situated below those which give origin to the motor fibers of the vagus. The bulbar fibers join the vagus in the jugular foramen and are distributed, as already mentioned, in the pharyngeal and recurrent branches of the latter nerve; these fibers of the accessory nerve innervate the muscles of the larynx, with the exception of the cricothyroid, the

glossus muscles, and the intrinsic muscles of the tongue.

THE PATHWAYS FOR VOLUNTARY MOTOR IMPULSES

The pathway taken by an impulse in passing from the cerebral cortex to a muscle innervated by a spinal nerve consists of two sections: the upper motor neuron, i.e., a cell of the motor cortex and its axon which, of course, reaches the muscle via a ventral root and a spinal nerve.

The corticospinal fibers pass from their origin (Betz cells of the motor area of the cerebral cortex, p. 887) through the white matter of the hemisphere. Converging as they descend they meet together with fibers ascending to the corpus callosum, forming here a fan-like structure known as the *corona radiata*. The pyramidal fibers then stream through the corpus striatum forming here a compact bundle known as the *internal capsule*. In the midbrain they occupy, on each side, the middle two-fifths of the base of the cerebral peduncle. In their descent through the pons they become broken up into several smaller bundles by the fibers of the pontine nuclei, but are collected together again at the lower level of the pons and continued downwards as a rounded column (the pyramid) on the ventral aspect of the medulla. At the lower end of the medulla the tract divides into two bundles of unequal size. The larger one (the crossed pyramidal tract) contains four-fifths of the total number of fibers and decussates with the corresponding bundle of the opposite side. The smaller bundle descends uncrossed (the direct pyramidal tract, see p. 855).

The corticospinal part of the pathway is considered as the *upper motor neuron*, the anterior horn cell and its axon as the *lower motor neuron* (see p. 855). The manner in which the upper and lower motor neurons are connected, and the convergence upon them of impulses from higher levels, e.g., red nucleus, superior colliculus, labyrinth, cerebellum, have been touched upon in the account of the sensory tracts in the cord. The motor neuron as a part of the reflex arc has been dealt with in Chapter LXV.

The fibers passing from the lower part of the motor area of the cortex to the cranial motor nuclei constitute the *corticobulbar tract*. This has precisely the same relationship to the cell of origin in the cerebral cortex as does the corticospinal

FIG. 366. Diagram of the motor nuclei of the cranial nerves and their cortical connection (in part after Ranson).

muscles of the pharynx and those of the soft palate, with the exception of the tensor veli palatini (which is supplied by the 5th nerve). The *spinal part* is composed of the axons of a group of cells in the anterior gray column of the cord extending from the 1st to the 5th or 6th cervical segment inclusive. These fibers supply the sternomastoid and trapezius muscles.

The hypoglossal nerve

The hypoglossal nerve is also purely motor. Its fibers are derived from a nucleus situated near the mid-line in the floor of the fourth ventricle and medial to the nucleus ambiguus. It supplies the thyrohyoid, styloglossus, hyoglossus and genio-

the anterior horn cells of the cord. The corticospinal fibers, however, cross at various levels throughout the brain stem. (See fig. 366.) The nuclei of the motor cranial nuclei are, of course, the motor neurons of the pathway from the cerebral cortex to the muscles of the face, tongue, larynx, etc.

THE INTERNAL CAPSULE

In a horizontal section of the cerebrum, the internal capsule is seen as a compact band of white matter lying between the thalamus and the caudate nucleus on its inner aspect and the lentiform nucleus on its lateral aspect (cf. fig. 367). In addition to the corticospinal and corticobulbar tracts, the following descending and ascending tracts compose it:

Descending:

Frontopontine tract, from frontal lobe (premotor cortex, p. 888) to pontine nuclei.

Temporopontine tract, from temporal lobe to pontine nuclei.

Corticorubral tract, from frontal lobe to the substantia nigra.

Frontothalamic tract, from frontal lobe to the nucleus of the thalamus.

Corticostriate fibers, from the premotor area to the caudate nucleus and, possibly, to the globus pallidus.

Ascending:

Thalamofrontal tract—fibers from the lateral anterior thalamic nuclei to the frontal cortex.

Thalamic radiation—fibers passing from the nucleus of the thalamus to the somesthetic post central convolution).

Auditory radiation—fibers passing from the geniculate body to the superior temporal convolution.

Optic radiation—fibers passing from the lateral geniculate body to the occipital lobe (calcarine area).

Rubro cortical fibers.

The internal capsule is bent to form a convexity medially. The region of the angle so produced is called the knee (genu). The portions in front and behind the knee are referred to as the anterior and posterior limbs, respectively. The anterior limb is between the caudate and the lentiform nuclei, the posterior limb between the thalamus and the lentiform nucleus. The anterior limb is occupied by the frontopontine, thalamofrontal, frontothalamic tracts and corticostriate fibers. The knee and anterior three-fourths of the posterior limb transmit the corticobulbar and corticospinal tracts, the former lying in front of the latter. The fibers of the corticospinal tract are divided into groups correlated with different mus-

cular regions, those carrying impulses to the upper parts of the body being placed anterior to groups innervating the lower limbs, and those controlling the proximal muscles of a given limb in front of those governing the more distal muscles.

The remainder of the posterior limb of the internal capsule is occupied by the temporopontine tract and the thalamic, auditory and optic radiations in this order from before backwards. The position of the cortico-rubral tract will be seen from figure 367.

A COMPARISON OF THE EFFECTS PRODUCED BY INJURY TO THE UPPER AND LOWER MOTOR NEURONS, RESPECTIVELY

The effects following interruption of conduction over the upper motor neuron differ in a characteristic fashion from those resulting from injury or disease of the lower motor neuron.

Disease or injury of the upper motor neuron

The following is a summary of the characters of a paralysis resulting from a lesion of the upper motor neuron (corticospinal pathway):—

(1) Hypertonia (spasticity) of the paralyzed muscles.

(2) Exaggeration of tendon reflexes, knee jerk increased, ankle clonus present.

(3) Positive Babinski response (p. 872).

(4) No permanent wasting, except as a result of prolonged disuse.

(5) Absence of the reaction of degeneration.

The corticospinal pathway is most commonly injured as the result of a vascular lesion, hemorrhage or thrombosis (usually of a lenticulo-striate branch of the middle cerebral artery) within the internal capsule. The lesion is usually unilateral and its effects involve the muscles on the opposite side of the body. The condition is termed *hemiplegia*. After the state of shock, which lasts for a variable number of days following the injury, has passed off, the following features are observed:

(1) **LOSS OR IMPAIRMENT OF VOLUNTARY POWER**, involving the muscles of limbs, trunk and face of the opposite side is evident. There is often little or no actual paralysis, merely a muscular weakness (paresis). The finer movements, such as those of the hands and fingers are especially affected. The volitional movements of the lower part of the face are involved to a greater degree than those of the upper, e.g., raising the eyebrows and closure of the eyelids, the reason being, very probably, that the part of the facial nucleus governing the latter movements receives fibers from both hemispheres. When voluntary efforts are made to

move the lower part of the face, as in showing the teeth, or pursing the lips, marked impairment of muscular power may be evident, yet emotional expressions, e.g., laughing, smiling or crying, though involving the same muscles may show little departure from the normal. For example, the patient, though unable to raise the corner of his mouth when asked, may smile naturally a moment later. The impulses which bring about movements of the facial muscles in these more automatic movements of facial expression apparently travel by other than pyramidal pathways (p. 874).

(2) MOVEMENTS OF THE JAW, TONGUE AND SOFT PALATE on the opposite side to the pyramidal lesion show some weakness but since they are

electrical reactions (p. 780) are normal also the premotor area of the cortex (LXIX.)

(4) REFLEXES. The tendon jerks at knee and elbow are exaggerated on the hemiplegic side and there may be ankle clonus. The response is "Extensor" in type¹ the abdominal cremasteric reflexes (p. 873) are abolished.

The upper motor neuron may be injured by injury or disease (hemorrhage, tumor) at any part of its course from the cerebral cortex to the spinal centers. The effects, though varying in degree, are the same as those described above. The general features just described, e.g., impairment of muscular power, hyperreflexia, exaggerated reflexes, present certain

FIG. 367. Diagram of the internal capsule. C. R. = corticobulbar tract.

bilaterally innervated this, as a rule, is not pronounced. There may be some deviation of the jaw upon opening the mouth, and of the tongue when protruded, to the hemiplegic side. The soft palate is lower on the hemiplegic side and the uvula tends to be drawn away from this side (i.e., toward the side of the cerebral lesion).

(3) HYPERTONIA OF THE MUSCLES—SPASTICITY. This involves on the paralyzed side the flexors of the elbow, wrist and fingers, adductors of the shoulder and pronators of the forearm. In the lower limb the extensors of the hip and knee, the adductors of the hip and the plantar flexors of the ankle are hypertonic. The attitude resulting from this distribution of the hypertonia has been compared to the decerebrate rigidity of animals (p. 824). The muscles do not waste and the

peculiar to the level of the lesion. The latter implicates the tract where, as in the internal capsule, the fibers form a compact bundle. The peripheral effects are likely to be more variable, i.e., to be *hemiplegic*, than when the lesion is in the cerebral cortex or the corona radiata. Then the paralysis tends to be more localized. It may affect only one limb—*monoplegia*—when the lesion interrupts the fibers of the corticospinal tract above the nuclei of the motor cranial nerves (supranuclear lesion) the muscles innervated by the latter will, of course, be involved as well as those above with the muscles of the limbs. The fibers from the cortex to the spinal centers cross at different levels but all above the level of the corticospinal fibers. If,

¹ This is in reality a flexor reflex (see p. 874).

involves the pyramidal pathway below, say, for the seventh cranial nerve but above decussation of the corticospinal fibers the lesion will involve the limbs and trunk of the opposite side and perhaps those of the tongue, face and throat, but the facial muscles will be spared. When the lesion involves the facial

3. Diagram illustrating the effects of lesions at different levels. 1, lesion of cortex causing monohemiplegia, depending upon its extent; 2, lesion of internal capsule, hemiplegia; 3, lesion of midbrain involving pyramidal fibers and nucleus of third nerve (Weber's paralysis); 4, lesion in pons involving pyramidal fibers and nucleus of facial nerve, hemiplegia with homolateral facial paralysis; 5, lesion in medulla involving pyramidal fibers and nucleus of hypoglossal nerve, crossed hemiplegia and homolateral paralysis of lingual muscles; 6, transection of spinal cord, paraplegia. (In part from Volzger and from Ranvier.)

nerve together with the pyramidal tract, hemiplegia results. This is paralysis of the limbs and trunk of the spastic type on the opposite side to the lesion, together with the paralysis of the lower neuron type on the same side to the lesion. Similarly, the hypoglossal may be involved together with the pyramidal tract above its decussation. Wasting and

paralysis of the tongue muscles on the same side as the lesion, and spastic paralysis of the limbs on the opposite side will result. Again, the glossopharyngeal nucleus may be implicated with consequent paralysis of the stylopharyngeus and loss of sensation over the posterior third of the tongue. The oculomotor nerve nucleus, since it lies in close proximity to the pyramidal tract, is also sometimes involved with the latter. The level of the lesion would then be indicated by paralysis of the ocular muscles innervated by the third nerve on the side of the lesion and hemiplegia on the opposite side. This is known as Weber's paralysis (fig. 362).

It is evident that the paralysis is more likely to be bilateral if the lesion is situated in a region where, as in the brain stem or spinal cord, the corticospinal tracts of the two sides are approximated, than if it is located at a level where these tracts are widely separated, as in the corona radiata or internal capsule; then unilateral effects are usual. Injury to the crossed pyramidal tract on one side of the cord, should it occur, will result in paralysis of the muscles on the same side. Complete interruption of both pathways in the cord will of course result in paralysis on both sides of the body below the level of the lesion—paraplegia (p. 870).

LESIONS OF THE LOWER MOTOR NEURON

Destruction of the motor cells situated in the anterior horns of the cord or of the motor nuclei of the cranial nerves, of the anterior spinal nerve roots or of the peripheral nerve trunks, results in complete paralysis of the muscle fibers supplied by the injured neurons. The paralysis is of the flaccid type, of which the following are the main clinical features.

- (1) Muscular hypotonia.
- (2) Loss of tendon reflexes.
- (3) Atrophy (wasting) and degeneration of muscles.
- (4) Electrical reaction of degeneration (p. 780).

The flaccid paralysis does not, as in lesions of the upper neuron, show a hemiplegic distribution. When the lesion involves the anterior horn cells as in anterior poliomyelitis, or the anterior roots of the spinal nerves, the paralysis assumes a segmental pattern. Individual muscles or scattered groups of muscles are commonly involved. Injury to the anterior horns usually results in a bilateral paralysis, though different muscles on the two sides of the body may be affected. Furthermore, since a given muscle receives its innervation from

more than one spinal segment, and conversely a single spinal segment supplies parts of several muscles (p. 848), a localized lesion of the cord may result in the paralysis of fibers scattered throughout several muscles, leaving other fibers in the same muscles intact. Weakness rather than complete paralysis of certain muscles will result. Even when the lesion involves several spinal segments, the muscles innervated by those at the upper and lower limits of the spinal region involved, will show partial paralysis, since they will still be supplied by undamaged nerve fibers from adjacent healthy segments.

The entrance of the ventral roots into the formation of the brachial and lumbar plexuses is accompanied by a regrouping of their constituent fibers which are continued into the various peripheral nerve trunks. A lesion of a peripheral nerve, therefore, produces a paralysis which is non-segmental in character. It corresponds to the distribution of the muscular branches of the nerve.

Cutaneous sensory loss will show a segmental pattern when the posterior roots of the spinal nerves are involved, but when the peripheral nerve trunk is implicated the distribution of the sensory defect will conform to that of the cutaneous branches of the nerve (see also figures 358 and 359). Injury to the ascending tracts in the cord will, of course, cause sensory loss below the level of the lesion (p. 851) and will vary in kind according to the particular fibers which have been interrupted.

FUNCTIONAL, MORPHOLOGICAL AND CHEMICAL CHANGES IN DENERVATED MUSCLE

A lesion involving any part of the lower motor neuron—anterior horn cell or axon—such as may result, respectively, from poliomyelitis or peripheral nerve injury, is followed by degenerative changes which extend to and include the nerve terminals within the muscle. A muscle thus completely denervated exhibits constant, fine, rapid, rhythmical contractions. This so-called fibrillation of the denervated muscle does not appear until several days after the abnormal electrical reactions (reaction of degeneration, p. 780) have already developed and complete degeneration of the nerve has occurred. The muscle fibers contract asynchronously; the contractions involve only a part of the length (0.5 to 1 mm.) of the fiber and give rise to small irregular action potentials. The fibrillation can sometimes, though not commonly, be seen through the skin. Having once appeared, fibrillation persists for a year or more and until the contractile elements have undergone complete atrophy. According to

Denny-Brown, a reduction in tension develops in the muscle when stimulated maximally can be detected within 2 minutes after section of the nerve, but investigators have been unable to observe any loss of contractile force until after a much longer interval (30–40 hours). An outstanding functional effect of denervation is the great increase in the sensitivity of the muscle to the intravenous or intra-arterial injection of acetylcholine. Normal muscle is excited by an intra-arterial injection of from 0.2 to 2.0 mg. of acetylcholine, whereas denervated muscle responds to a dose of from 0.002 to 0.02 γ . It is generally believed that this hypersensitivity to acetylcholine is responsible for the Vulpian and Sherrington effects, and most probably also for the "fright reaction" described by Bender (p. 947). The denervated muscle is hyperexcitable, though to a less pronounced degree than to potassium chloride.

The denervated muscle soon commences to atrophy, a reduction in its bulk becoming apparent within a few days after section of the nerve. Atrophy progresses rapidly and is followed by degeneration of the contractile elements. Microscopic changes in the muscle fibers consist of swelling and vesiculation of the myofibrils, a reduction in sarcoplasm, and fading, followed by the disappearance of the striations of the myofibrils. Ultimately all contractile tissue disappears and is replaced by fibrous tissue and fat. As these morphological changes are occurring, the muscle gradually loses its plastic or ductile quality, flexors and adductors shorten and become more or less "set" in their positions. The antagonistic muscles lengthen correspondingly. This state of the muscles is called *contracture*.

The chemical changes in denervated muscle consist of a reduction in glycogen, phosphocreatine and adenosinetriphosphate, but they do not become pronounced until the onset of fibrillation. The breakdown of glycogen and subsequent resynthesis of glycogen by the denervated muscle during a work period is normal for a few days following nerve section but when fibrillation supervenes the ability of the muscle to restore its glycogen stores after contraction is greatly impaired. The atrophic muscle shows a large increase in calcium, a small increase in chloride, and a decrease in potassium. Changes in chloride and potassium can be accounted for by the reduction in muscle mass and its replacement by interstitial tissue. The increase in calcium is great, however, to be explained entirely in this way.

The cause of fibrillation in denervated muscle is unknown, but it is not improbable that it is a manifestation of its hypersensitivity to acetylcholine. The observation of Magladery and Solandt that quinine, which abolishes acetylcholine hypersensitivity, suppresses fibrillation is highly suggestive; yet Auer and his associates have shown, direct stimulation of denervated muscle does not cause the release of acetylcholine. It follows, therefore, that if the stimulant effect of this agent is responsible for fibrillation, the agent must be carried to the muscle in the blood stream.

ased sensitivity to acetylcholine may be due to a of cholinesterase for, according to Marnay and hmansohn, this enzyme, which normally is con- cated in the neighborhood of the nerve endings in tal muscle, disappears after denervation. The of cholinesterase might also explain the failure of pe to cause anything more than a transient aug- mentation of fibrillation.

ge atrophy following nerve degeneration has not explained satisfactorily. Langley and Kato ved that the ceaseless activity of the fibrillating le was the primary cause, thus attributing it to work and exhaustion. Though other investigators incline to this view it has not received general tance. One reason for questioning this explana- is that the tension developed by the fibrillating le is less than that of the ordinary tonic contraction rmal muscle, yet the oxygen consumption of the vated muscle is greater than that of normal ols. One would not expect atrophy to result r such conditions. There is little evidence for the r belief in trophic nerves in the original meaning e term, namely, that certain nerve fibers exerted a ic nutritional or trophic control over the muscle. e sense that denervation is followed, among other s, by profound nutritional changes in the muscle, he motor nerves do serve a trophic function, but a function is thought to be secondary or incidental an than constituting a direct and essential action the muscle fiber.

SECTION OF THE CORD. BROWN-SÉQUARD'S Syndrome . PARALYSIS

esion which completely interrupts the con- y of one-half of the cord causes the following hances:

I. Motor paralysis

per neuron type of paralysis of the muscles the level of the lesion and on the same side s as a result of the severance of the cortico- tracts. The muscles supplied by the seg- actually implicated in the lesion will, as a of destruction of the anterior horn cells, t a flaccid paralysis (lower motor neuron The flaccid paralysis is, however, small in unless the lesion involves the cervical or r enlargements (fig. 369).

II. Vasomotor paralysis

a result of the interruption of pathways in lateral funiculus connecting the vasomotor with the spinal sympathetic centers (cells al horn) dilatation of the cutaneous vessels and on the side of the lesion occurs. The of the paralyzed side is at first redder and

warmer than normally; later it becomes cyanosed and cold.

III. Sensory changes

(a) *Sense of position and movement and of tactile discrimination* (compass test), being mediated by fibers of the posterior funiculus which do not cross, are lost below the level of and on the same side as the lesion. The loss of the sensations from the muscles and joints causes ataxia on the side of the lesion. The non-sensory impulses from the muscles since they pass to the cerebellum by two paths (direct and indirect spinocerebellar) are not completely interrupted on either side. The partial blocking of these impulses, however, contributes to the ataxia.

FIG. 369. Diagram showing effects following hemi-section of the cord in the lower thoracic region.

(b) *Painful and thermal sensations* are conveyed by fibers which cross shortly after their entrance into the cord (lateral spinothalamic tract). As a result of the destruction of these fibers before their decussation, a narrow zone of skin at and just below the level of the lesion and on the same side, shows analgesia and thermoanesthesia. The rest of the body below the lesion and on the same side shows no such loss, but as a result of the destruction of fibers after crossing, pain and temperature are completely lost on the opposite side. Owing to this fact, that some fibers mediating these sensations ascend for a segment or two before crossing, the appreciation of pain and temperature is retained in a zone on the contralateral side just below the lesion. This zone corresponds in extent to that of analgesia and thermoanesthesia on the homolateral side.

(c) *Touch and tactile localization.* It has been pointed out (p. 853) that fibers mediating these sensations cross at different levels in the cord. Therefore, a unilateral lesion of the cord interrupts fibers which have crossed from the opposite side of the body as well as those ascending from the same side, i.e., uncrossed fibers of the posterior columns. These sensations on the side of the lesion are still mediated, however, by fibers which have escaped destruction through having crossed below the lesion to the ventral (anterior) spinothalamic tract of the uninjured side; while those from the side opposite to the lesion are carried by the fibers of the posterior columns of that side. The sensations of touch and tactile localization, therefore, are not lost on either side of the body as a result of a unilateral lesion of the cord, though some impairment on the same side as the lesion may be detected. A narrow zone above the lesion on both sides is hypersensitive to touch, pain and thermal stimuli (hyperesthesia). This is probably an irritative phenomenon; it is usually transitory.

SYRINGOMYELIA

This commences as a proliferation of neuroglia (gliosis) in the spinal gray matter. The newly formed tissue breaks down with the formation of cavities filled with a gelatinous material. The process may extend for considerable distances up and down the cord. The starting point of the disease is most frequently the base of the posterior gray column. The lower cervical and upper thoracic regions are most commonly affected. The disease may extend into the bulb (syringobulbia) when signs of implication of the cranial nuclei appear.

Dissociated sensory loss and muscular weakness with a segmental distribution are among the characteristic features of the disease. Owing to the site of the changes, the fibers mediating pain, heat and cold, where they make connections with the cells of the posterior horns, are first destroyed. If the lesion is unilateral, thermoanesthesia and analgesia of the skin supplied by, and on the same side as the diseased segments result. Other sensations, e.g., touch, muscle sense, are unaffected until later in the disease. Involvement of the spinal nucleus of the trigeminal results in the characteristic sensory loss over the face, the areas supplied by the ophthalmic, maxillary and mandibular divisions being affected successively in this order (p. 858). When both dorsal horns are involved, or as a result of expansion of the cavity the anterior gray commissure is pressed upon and the fibers injured at their point of crossing, the thermoanesthesia and analgesia are bilateral. The muscles innervated by the diseased segments become weak and wasted; these effects often appear first in the small muscles of the

hand. So long as the disease does not cause injury to the white matter, the sensory and motor effects are limited and have a segmental distribution. Involvement of the corticospinal tracts will result in spasticity below the level of the lesion, while pressure upon the spinothalamic tracts and dorsal columns will be followed by sensory loss below the level of the lesion. The degree of sensory loss, its type and distribution and whether homolateral or contralateral vary according to the extent to which the individual tracts are affected by the disease. As a result of the loss of the protective sensations (pain and temperature), subjects of syringomyelia are prone to suffer injuries which, not being perceived at the time, are neglected and ultimately lead to serious lesions, e.g., painless disorganization of a joint (arthropathy, Charcot's joint). Involvement of the sympathetic centers in the lateral columns lead to vasomotor disturbances, excessive sweating or absence of sweating, cyanosis, etc. So-called trophic disturbances, e.g., ulcers, whitlows, gangrene, etc. are largely the result of vasomotor abnormalities and the loss of sensation which, as just mentioned, permits an injury, trivial perhaps at first, to be disregarded.

SUBACUTE COMBINED DEGENERATION OF THE CORD

This condition involves the white matter of the cord and is almost always associated with pernicious anemia. The degenerative process consists of breakdown of the myelin sheaths, subsequent destruction of the axons and their replacement by newly formed glial tissue. The changes are most pronounced in the corticospinal and cerebellar tracts and in the posterior columns. The spinothalamic tracts, as a rule, are involved to a less degree. The chief clinical features are, therefore: (a) muscular weakness and spasticity, (b) impairment of the sense of position and passive movement of the limbs with consequent ataxia and a positive Romberg sign, (c) loss or impairment of sensitivity to touch, pressure, localization, spatial discrimination, vibration, pain and temperature. The relative extent to which these sensations are lost is variable. The cutaneous sensory loss is at first of the distal regions of the extremities—hands and wrists, feet and ankles. Paresthesias (tingling, pricking and burning sensations) frequently precede the sensory loss. (d) The reflexes vary. The tendon jerks are frequently exaggerated as a result of involvement of the corticospinal tracts, but they may disappear as the disease progresses. The plantar response is usually of the "extensor" type, especially in the later stages.

The severity of the nervous manifestations does not always run parallel with that of the blood picture; neurological features may be pronounced though anemia is of mild degree, or vice versa. It is commonly stated that subacute combined degeneration of the cord may progress though the blood picture is restored to normal as a result of treatment with liver extract.

It has been shown, however, by Farquharson and Graham that if the dosage of liver extract is increased considerably above that which will keep the anemia in abeyance, the nervous condition shows marked improvement. Strauss and his associates also state that in their experience the progress of the degenerative lesion in the cord can be completely arrested by the administration of liver extract, provided that the dose is sufficient to maintain a red cell count of 4,500,000, a mean corpuscular volume of less than 100 cu. microns and a color index of 1.0 or lower.

TABES DORSALIS, LOCOMOTOR ATAXIA

In this condition, which is the result of syphilis, the fibers of the dorsal roots after their entry into the cord (i.e., the central processes of the primary sensory neurons) are attacked. The ganglion cell bodies of the dorsal roots, as a rule, are not affected. The essential lesion within the cord, therefore, involves the entrance zone of the lateral division of the dorsal roots (dorsi-lateral fasciculus of Lissauer), and the dorsal fasciculi (gracilis and cuneatus). The endogenous fibers of the cord escape, but although it is those tracts composed of exogenous fibers which are specifically attacked by the disease, the functions of the cerebellar and spinothalamic tracts are also seriously disturbed as a result of degeneration of the primary neurons leading to them. The descending tracts remain as a rule practically unaffected. The reason for the selective destruction of the exogenous fibers of the cord is unknown; possibly it is compression of the fibers by proliferation or inflammatory swelling of the meninges at the point of entrance of the posterior root. The central fibers of the trigeminal nerve which are homologous with the fibers of the posterior spinal nerve roots may also be implicated.

The sensory changes are those which might be expected to result from a gradual degeneration of dorsal root fibers.

The chief manifestations are as follows: (a) During the degenerative process paresthesias of various types, hyperesthesia and stabbing pains are common. (b) Impairment, or loss to a variable degree, of all forms of sensation follows. Loss of the sense of position and of passive movement, and blockage of afferent cerebellar impulses result in marked incoördination of the muscles—ataxia. Movements are jerky, exaggerated and imperfectly controlled, the subject being unable to move his hands and feet in the desired direction or to assume a given position at will, e.g., bringing his finger to the nose or placing the heel of one foot upon the toes of the other. The gait is ataxic, the feet are kept wide apart, raised unnecessarily high and brought down in a stamping fashion; the patient may learn to overcome this tendency by shuffling.

Involvement of sensory cranial fibers causes corresponding inoördinate actions of the facial, ocular and lingual muscles. When standing with the eyes closed the patient, being thus deprived of an important

aid in maintaining his equilibrium, tends to sway and may fall (Romberg's sign). (c) The interruption of the pathways for proprioceptive impulses from the skeletal muscles (p. 822) results in extreme *hypotonia*. (d) The *tendon reflexes* are abolished as a result of the destruction of the afferent limb of the proprioceptive reflex arc. The abdominal reflexes are present. (e) "*Lightning pains*" and *trophic disturbances*. The former are severe stabbing paroxysmal pains usually localized to an area supplied by one or more spinal segments. Vasodilatation, small hemorrhages or herpes zoster may occur in the painful area. These vascular and cutaneous effects have been attributed to antidromic impulses reaching the periphery via sensory fibers. The skin of the affected area may break down with the formation of so-called trophic ulcers. Painless destruction of joints (Charcot's joint) is not uncommon in tabes. The loss of the sense of pain which causes the patient to suffer injuries of which he is unaware, the extreme hypotonia of the muscles which normally support the joint, and the vascular disturbances resulting from damage to autonomic fibers combine to produce such joint conditions. They are usually classed among the trophic disturbances, the term implying that the interruption of trophic impulses is responsible. However, the existence of true trophic fibers, i.e., specific fibers which preside over the nutrition of the peripheral tissues, is questionable. (f) *Tabetic crises*. These are apparently the result of the involvement of afferent autonomic fibers which enter the cord by the dorsal roots. They consist of paroxysmal attacks of pain and functional disturbances in one or other of the viscera. Gastric crises are the commonest. They consist of severe epigastric pain and vomiting. *Rectal crises* consisting of pain in and increased activity of the rectum, *vesical crises* with bladder pain and difficult urination or *laryngeal crises*, in which spasm of the adductors of the larynx with dyspnea may occur. (g) *Ocular signs*. The pupils are as a rule constricted and often unequal. The Argyll-Robertson pupil (p. 1014) in which the reflex to accommodation is retained but the reaction to light is lost, is a characteristic ocular feature of tabes. The pupil also frequently fails to respond by dilatation to stimulation of the skin of the neck (cilio-spinal reflex). The loss of this reflex is usually attributed to degeneration of the central sympathetic pathway through which the dilator pupillae muscle is innervated (p. 1012). Some drooping of the upper lid (ptosis) may also result from the blockage of sympathetic pathways which normally transmit impulses to the smooth muscle in this situation; compensatory contraction of the frontalis muscle with wrinkling of the skin of the forehead results. Damage to the fibers of the 3rd, 4th or 6th nerves results in paralysis of the ocular muscles, the external rectus most commonly. Squint and double vision (diplopia (p. 1018)) are consequences. Primary optic atrophy occurs.

COMPLETE TRANSVERSE DIVISION OF THE CORD

A sudden, or rapidly progressive, complete interruption of the continuity of the cord may result from injury (e.g., gunshot wound, fracture-dislocation of the spine, etc.) or from acute inflammation (e.g., transverse myelitis). Immediate and complete loss of voluntary power below the level of the lesion results. Paralysis of both lower limbs resulting from this or any other nervous lesion is spoken of as *paraplegia*. Complete division of the cord in the lower cervical region will result in paralysis of all four limbs, *quadriplegia*. A lesion of this nature in the upper cervical region is of course rapidly fatal since the diaphragm and other respiratory muscles are isolated from the respiratory center. The subsequent history of the subject of a complete transverse spinal lesion has been divided into three stages by Riddock.

I. Stage of spinal shock

Immediately following the injury there are, complete loss of visceral and somatic sensations, and flaccid paralysis below the level of the lesion. The skeletal muscles are quite toneless. The tendon jerks, plantar response and abdominal reflexes are abolished. The cremasteric and bulbocavernosus reflexes, though absent as a rule, may at times be elicited. The anal reflex is present. A zone of heightened sensitivity (hyperesthesia) immediately above the level of the lesion is present and spontaneous pains in this region, or a feeling of tightness encircling the body may be experienced by the patient. There is retention of urine and feces due to tonic contraction of the sphincters. This stage is analogous to the state of spinal shock in lower animals but is much more severe and prolonged. In the dog or rabbit, for example, flexor reflex activity is retained and the knee jerk is elicitable within half an hour or less after spinal transection (p. 828). In man spinal shock lasts for from one to three weeks.

II. Stage of reflex activity—*paraplegia in flexion*

Recovery of the isolated spinal centers; the flexor muscles gradually regain a part of their lost tone. The first reflex to appear is the so-called extensor response or sign of Babinski. At this time the abdominal (rectus muscles) and other superficial reflexes can also usually be evoked with ease. Later the tone of the extensor muscles is restored to some extent and the tendon jerks reappear. The knee jerk returns usually in from 3 to 7 weeks after the injury and may become somewhat

greater than normal, but shows certain abnormal features. The extension of the knee is not maintained in the normal way for a brief period; instead the quadriceps after its contraction relaxes suddenly again and allows the leg to fall like a dead weight. The ankle jerks are weak or may not appear at all. Clonus is very rarely obtained. It will be recalled that in the spinal animal, though flexor reflex activity is brisk after spinal transection, extensor reflexes, apart from the knee jerk which returns promptly, are restored very slowly. "Spinal man" also shows a preponderance of the flexor reflexes. The flexor responses are, as mentioned above, well-developed before the knee jerk appears and become progressively more active, whereas, extensor responses, for the most part cannot be elicited. Stroking the skin of the sole, for example, will result in a response involving a number of flexor muscles accompanied by inhibition of their antagonists. Sometimes contraction of the extensors of the opposite limb (crossed extensor reflex, p. 819) occurs. When the stage of reflex activity is fully developed, spontaneous reflex spasms of paralyzed limbs occur and quite a mild stimulus applied to the paralyzed limbs or to the genital region results in a wide-spread reflex contraction of flexor muscles. This response, which has been called the "*mass reflex*" by Head and Riddock, will be considered more in detail presently. In this stage the bladder and rectum empty automatically. Though the tone of all muscles is lower than normal, the flexors are less hypotonic than the extensors, and the limbs tend to be drawn into flexed positions. The paralyzed state is therefore referred to as *paraplegia in flexion*. The duration of the stage of reflex activity is indefinite. The tracts whose destruction is essentially responsible for the features of paraplegia in flexion are the corticospinal and vestibulospinal. It will be remembered that the extensor dominance of the decerebrate animal is abolished, whereas flexor responses are retained and may even be increased after destruction of the vestibular nuclei.

III. Stage of failure of reflex activity

This stage is ushered in when, as a result of some infective complication (e.g., bed-sores, cystitis, pyelitis, etc.) and the consequent absorption of toxins, the spinal reflex centers are rendered functionless. As a rule it precedes death by a short interval. The extensor reflexes (e.g., knee jerk) are the first to disappear. Then the flexor

ponses are elicited with gradually increasing difficulty and the "mass reflex" does not occur. Finally all reflex activity is abolished and the muscles waste. Retention of urine and feces occurs, or there may be continual dribbling of urine, and fecal incontinence. Degeneration of the cells of the spinal gray matter, as a result simply of their isolation from higher centers (isolation dystrophy) which, according to Sherrington, occurs in the spinal monkey, does not apparently occur in spinal men for, as mentioned above, the stage of reflex activity may in the presence of infective conditions continue for indefinitely long periods. If toxemia commences in the first stage (spinal shock) this may merge into the third stage, the second stage of reflex recovery being absent.

INCOMPLETE DIVISION OF THE CORD

A bilateral lesion destroying the pyramidal tracts above the lumbar region but leaving the vestibulospinal fasciculi intact causes *paraplegia in extension*. The muscles are spastic and extensor activity predominates. The tendon jerks are exaggerated and patellar and ankle clonus can be readily elicited. Whereas paraplegia in flexion is analogous to the spinal state of animals, paraplegia in extension is more comparable to extensor rigidity. The "extensor" plantar response, which in reality a flexor protective reflex, is present, but much less intense and involves fewer muscles, than that seen in paraplegia in flexion. It is accompanied by a crossed extensor reflex. The mass reflex is absent. The abdominal reflexes are absent. Paraplegia in extension will also result from a bilateral lesion of the corticospinal tracts throughout any part of their course from the cortex downwards, and in a unilateral lesion (hemiplegia) the features are of the same nature. On the other hand, a lesion of the cord even though incomplete, if it involves the vestibulospinal tracts as well as the pyramidal, gives rise to the features characteristic of paraplegia in flexion.

The "mass reflex"

This, as already mentioned, occurs in conditions in which reflex activity predominates and when the spinal centers which had been released from higher control establish independent activity. A relatively weak stimulus causes, as a result of irradiation within the cord, a diffuse reflex response in which are included a large number of voluntary muscles as well as the musculature of certain viscera. The response shows no "local sign," i.e.,

there is no circumscribed area from which it is elicitable alone, and it shows little or no modification upon varying the site of application of the stimulus. It can be evoked from anywhere over the limbs, genital regions or abdomen below the level of the lesion. The type of stimulus to which it responds is one which would be painful or unpleasant (e.g., scratching, pinching, pricking, etc.) could it be felt by the subject. It is an exaggeration of the normal withdrawal or protective reflex (flexion reflex, p. 819). The mass reflex comprises the following reactions:

(a) A *flexor spasm* of the muscles of the abdominal wall (recti) and lower extremities as a result of stimulation of the skin of the abdomen, genital region or limbs.

(b) *Sweating* caused by stimulation of the skin or of the vesical or rectal mucosae; its distribution is, roughly, that of the sensory loss.

(c) *Evacuation of the bladder*, even though only partially full, and of the *rectum* follows stimulation of the skin, or of the respective mucous surface. Evacuation of the bladder is affected normally by contraction of the detrusor muscle and relaxation of the sphincter (p. 412). Immediately after complete section of the cord the detrusor muscle may be capable of contracting reflexly as a result of the stimulus caused by distension of the bladder wall, but inhibition of the sphincter fails to occur, and retention of urine results. When, however, the sphincter is dilated by means of a catheter, the bladder wall contracts and evacuation occurs readily. After a time, relaxation of the sphincter, as well as contraction of the detrusor muscle, occurs through the reflex center in the sacral cord, when a sufficient quantity of urine (500 to 600 cc.) has collected to distend the bladder and so act as a stimulus. This reflex which characterizes the so-called *automatic bladder* and is brought about by intravesical stimulation is very readily facilitated by extra-vesical stimuli. Thus, as mentioned above, a scratch upon the sole of the foot or in the genital region causes a spasm of flexor muscles and, even though the quantity of urine present in the bladder at the time be quite inadequate to stimulate through distension alone, the extra-vesical stimulus has such a facilitating effect upon the vesical reflex that evacuation results. The facilitation caused by an extra-vesical stimulus is always more readily demonstrable upon the detrusor contraction (i.e., when a catheter is in position) than upon the sphincter. Though they have not been studied in the same detail the mechanisms con-

cerned in the reflex evacuation of the rectum are no doubt similar.⁴

THE PLANTAR REFLEXES

This is the most appropriate place to consider these and other superficial reflexes.

The *normal plantar response* to a light scratch applied to the skin of the sole is plantar flexion of the four outer toes with no movement, or, more usually, plantar flexion of the great toe. The toe movements are accompanied by dorsiflexion of the ankle and contraction of the tensor fasciae femoris. The center for the reflex lies in the first sacral segment; its physiological significance is unknown. In a lesion of the cortico-spinal tract at any level above the first sacral segment, the normal response is replaced by one in which *dorsiflexion* of the great toe and spreading or fanning of the outer toes occurs. This response is called after its discoverer the *sign of Babinski* (fig. 370). From the dorsiflexion of the great toe, which is due to the contraction of the extensor longus hallucis, this reflex is also frequently referred to as the *extensor response*.⁵ This term, however, is incorrect since the upward movement of the great toe is part of a general flexor response homologous with the flexor reflex elicitable from the hind limb of a lower animal (p. 819). The dorsiflexors of the toes, though classed anatomically as extensors must, when compared physiologically with similar muscles in the limb of an animal such as the dog, be included among the flexors. In lesions of the corticospinal tracts (e.g., hemiplegia, paraplegia in extension) in which extensor reflex activity overshadows the flexor reactions, the so-called extensor plantar response is minimal, consisting mainly of the toe movements just described. The flexor nature of the reflex is shown, however, by the associated contraction of the ham-strings, i.e., semitendinosus, semimembranosus and biceps femoris, which invariably occurs (see also p. 870). Even when the toe movements do not

occur, some slight contraction of the ham-string can usually be detected. Its flexor nature is also indicated by the fact that an undoubted extensor reflex such as ankle clonus is readily inhibited by evoking the Babinski reaction (reciprocal inhibition). In hemiplegia in which the Babinski sign is present, stimulation of the sole of the *sou* side in some instances causes *plantar* flexion of the toes on the affected side together with contraction of the extensors of the knee and hip. This crossed response differs, however, from the normal plantar response (which of course is not crossed) in that contraction of the tensor fasciae femoris (a flexor does not occur. It is looked upon as a *true* extensor response corresponding to the crossed extensor reflex in the hind limb of the experimental animal when a flexion reflex is set up in the homolateral limb.

FIG. 370. Upper drawing, normal plantar response; lower drawing, Babinski response.

In the restricted forms of the extensor response as seen in hemiplegia, the receptive field of the reflex is also strictly circumscribed, being elicitable only from the sole—the outer border or the base of the hallux more especially.

In paraplegia in flexion in which flexor activity predominates the so-called extensor response is maximal and, as we have seen, is simply part of a widespread flexor reaction. The receptive field of the reflex is extensive and the application of stimulus is followed by contraction not only of the extensor longus hallucis and ham-strings but by an associated contraction of the extensor longus digitorum, tibialis anticus, gracilis, sartorius, rectus femoris and iliopsoas. The extensors undergo reciprocal inhibition. The flexor nature of the “extensor” response is therefore undoubted. It is a nociceptive reflex, the limb, when the reflex is fully developed, being withdrawn from the

⁴Holmes has denied that the evacuation of the bladder in response to peripheral stimulation is an integral part of the mass reflex, i.e., due to irradiation of impulses to the micturition center in the cord; he attributes it simply to the sudden rise in intraabdominal pressure caused by the associated reflex contraction of the abdominal muscles.

⁵An “extensor” plantar response is present normally in infants up to the first year or so, i.e., to the age of walking, and is then probably due to the undeveloped state of the corticospinal tracts. It is also present in normal adults during deep sleep (p. 917) and in the apneic stage of Cheyne-Stokes respiration, being apparently due in the latter instance, to anoxemia of the motor cortex.

stimulating (nocuous) agent by a flexion at hip and knee and dorsiflexion at the ankle.

OTHER REFLEXES

(a) *Oppenheim's reflex* is simply a modified Babinski response; it is associated with the same conditions as the latter and has a similar significance. It consists in dorsiflexion of the hallux which results when a firm downward sliding pressure is applied to the skin overlying the tibia.

(b) *Rossolimo's reflex* consists of flexion of the toes in response to a sharp tap upon the ball of the foot (see p. 890).

(c) *Nociceptive reflexes of upper limb.* A flexor reflex of the upper limb corresponding to the sign of Babinski of the lower limb is often elicitable in lesions involving the pyramidal tracts above the thoracic region, as in hemiplegia. It consists of flexion of the fingers, often accompanied by flexion of wrist and elbow and abduction and external rotation of the shoulder, when a mildly nocuous stimulus is applied to the palm or surfaces of the finger. Sometimes an extensor response—elevation, adduction and internal rotation of the shoulder, extension of the elbow, pronation of the forearm, flexion of wrist and hyperextension and adduction of the fingers—may be elicited in pyramidal tract lesion by stimulation of the skin of the axilla or side of the chest.

(d) *Abdominal reflexes.* Lightly scratching the skin of the abdomen of a normal person causes a reflex contraction of the abdominal muscles. The reflex is abolished in pyramidal lesions or in one (e.g., acute anterior poliomyelitis) involving the centers in the cord. The latter are located in the 7th to 12th thoracic segments.

(e) *Cremasteric reflex* consists of contraction of the cremaster muscle and elevation of testicle which results from a light stroke applied to the skin on the inner aspect of the upper part of the thigh. It is abolished in pyramidal lesions or as a result of destruction of the center which lies in the 1st lumbar segment.

(f) *Bulbocavernosus reflex* has its center in the 2nd, 3rd and 4th sacral segments. It consists of contraction of the bulbocavernosus muscle (detected by palpation) in response to stimulation of the glans penis.

(g) *Anal reflex* is the contraction of the external anal sphincter in response to scratching the neighboring skin. Its center is situated in the 4th and 5th sacral segments.

(h) *Gluteal reflex.* Scratching the skin of the buttock causes contraction of the gluteal muscles. It depends upon the integrity of the 4th and 5th lumbar segments.

The *deep or tendon reflexes*, such as the knee jerk, ankle jerk, etc., have been discussed in Chapter LXVI.

CHAPTER LXVIII

THE EXTRAPYRAMIDAL SYSTEM. THE THALAMUS AND HYPOTHALAMUS. THE VISUAL AND AUDITORY PATHWAYS.

There are at least two pathways other than the pyramidal or cortico-spinal through which the cerebral cortex exerts an influence upon the activity of the skeletal muscles, namely through the pons and cerebellum—the *corticopontocerebellar*—and through the striate body and the subthalamic nuclei—the *corticostrionigral*. The first mentioned of these two systems will be considered in chapter LXXI. The second will be considered here.

The corticostrionigral system embraces four masses of gray matter, (a) *the corpus striatum*, (b) *the red nucleus*, (c) *the substantia nigra* and (d) *the body of Luys*, which are referred to collectively as the basal ganglia. These several nuclear masses are connected together by numerous fiber tracts (fig. 371).

THE CORPUS STRIATUM

The corpus striatum is a mass of gray matter lying at the base of the hemisphere in close relation to the thalamus. It is incompletely divided into two parts by the fibers comprising the internal capsule: (a) the *caudate nucleus* lying on the medial side of the anterior limb of the internal capsule, and (b) the *lentiform nucleus* occupying a corresponding position on the outer side of the internal capsule (fig. 367, p. 863). The wedge-shaped lentiform nucleus is divided again into an outer and an inner part, the *putamen* and the *globus pallidus*, respectively. On the outer side of the lentiform nucleus is a narrow band of white matter—the *external capsule*; lateral to this again is an elongated island of gray matter—the *claustrum*.

The fiber system of the corpus striatum. The fiber connections may be divided into the following groups:

(1) *Fibers arising and ending within the corpus striatum (internuncial).* These pass from (a) the putamen to the globus pallidus (b) from the caudate nucleus across the internal capsule to the putamen and (c) from the lateral to the medial zone of the globus pallidus, (fig. 372).

(2) *Fibers arising in the corpus striatum and ending elsewhere (striofugal fibers).* The great bulk of the fibers leaving the corpus striatum arise from the globus

pallidus. (a) *Striothalamic* from globus pallidus to the lateral nucleus of the thalamus. Through these, and the thalamo-olivary and olivospinal tracts a possible pathway exists for striatal impulses to reach the spinal cord. (b) *Striosubthalamic (ansa lenticularis).* These arise in the globus pallidus and pass to the red nucleus, substantia nigra and the body of Luys. (c) There is no direct connection, apparently, between the corpus striatum and the spinal centers through, according to Morgan, a direct path (strio-bulbar) to the bulbar nuclei exists. These fibers arise in the globus pallidus. They terminate around cells in the reticular formation of the pons and medulla and in the trochlear, abducens, trigeminal (motor), glossopharyngeal and hypoglossal nuclei, of the same and the opposite side. The reticulospinal and rubrospinal tracts provide pathways whereby striatal impulses reach the spinal centers. No fibers passing from the striate body to the cortex were found by Wilson, who made a comprehensive study of the striatal connections. Others, however, state that such exist.

(3) *Fibers ending in the corpus striatum but arising elsewhere (striopetal fibers).* (a) *Thalamus to caudate nucleus and globus pallidus.* (b) *Body of Luys to globus pallidus.* (c) *Red nucleus to globus pallidus.* (d) *Cortex to caudate nucleus.* Area 6 (premotor) sends fibers to this part of the corpus striatum and possibly also to the globus pallidus (Hardesty).

(4) *Fibers joining the corpora striata of the two sides (commissural fibers).* These pass from the globus pallidus of one side to the corresponding nucleus of the opposite side.

(5) *Fibers passing through the corpus striatum (fibers of passage).* Ascending and descending fibers of internal capsule—corticospinal, thalamocortical, etc. (see fig. 367).

The corpus striatum is also almost certainly in communication with the cerebellum through relay stations, e.g., red nucleus.

THE RED NUCLEUS

The red nucleus is a large oval mass of gray matter in the tegmentum of the mid-brain lying beneath the thalamus and extending backwards from about the middle of this structure to a level beneath the posterior border of the superior colliculus (figs. 371 and 372). The fibers of the third nerve stream through it. Two groups of cells are found within it. The cells of one of these

groups are large (*nucleus magnocellularis*) and are situated at the posterior part of the red nucleus. The other, situated anteriorly, is composed of small cells (*nucleus parvocellularis*). Phylogenetically,

bar and rubrospinal tracts. The connections of the red nucleus are:

- A. Efferent tracts (rubrofugal).
 (a) Rubrobulbar and rubrospinal tracts from nucleus

Fig. 371. Diagram of the corpus striatum and its connections.

Fig. 372. Diagram of section through the mid-brain at the level of the red nucleus.

the nucleus parvocellularis is a later acquisition. Fibers arising from the nucleus magnocellularis of one side issue from the ventral aspect of the red nucleus and, crossing with those of the opposite side (Forel's decussation) descend as the rubrobul-

magnocellularis to the motor cells of medulla and cord (p. 856).

(b) To the reticular formation of the pons and medulla (tractus rubroreticularis).

(c) Rubro-olivary tract, to the inferior olivary nucleus.

(d) Rubrothalamic tract to the lateral nucleus of the thalamus.

(e) Rubrostriatal to globus pallidus.

B. Afferent tracts (rubropetal).

(a) Corticorubral tract, from the frontal lobe and premotor area to the nucleus parvocellularis.

(b) Pallidorubral tract from the globus pallidus.

(c) Cerebellorubral tract (p. 924) composed of fibers which arise mainly in the dentate nucleus of the opposite cerebellar hemisphere and reach the cells of the nucleus magnocellularis via the superior cerebellar peduncle. This cerebellar pathway is relayed to the bulbar and spinal centers by the rubrobulbar and rubrospinal tracts.

Little is known definitely with regard to the functions of the red nucleus. It appears, however, to be an essential part of the mechanism controlling the performance of complex muscular movements. It may be regarded as a center wherein impulses received from various sources (cerebral cortex, corpus striatum, cerebellum, etc.) are organized before their transmission (via rubrobulbar, rubrospinal and rubroreticular tracts) to the motor centers of the cranial and spinal nerves.

THE SUBSTANTIA NIGRA

The substantia nigra is the crescentic gray mass seen in transverse section lying ventral to the red nucleus and between the basal and tegmental portion of the cerebral peduncles (figs. 371 and 372). It is composed of large cells which are deeply pigmented with melanin and have a high content of iron. It is connected by both afferent and efferent fibers with the globus pallidus and the frontal region of the cerebral cortex. It also receives fibers from the body of Luys and from the medial and lateral lemnisci, the superior colliculus and the mammillary bodies. It is thus in receipt of afferent impulses from the general body surface and from the organs of hearing, sight and smell. It sends fibers to the red nucleus and to the formatio reticularis of the pons. The substantia nigra is regarded as a center for the integration of those afferent impulses which are essential for the performance of skilled movements. It shows its greatest development in man and the higher apes.

THE BODY OF LUYS OR SUBTHALAMIC NUCLEUS

The anterior limit of this structure lies on a level with the mammillary bodies. It should not be confused with the hypothalamic nuclei (p. 882). It lies lateral and ventral to the red nucleus and dorsal to the substantia nigra. Fibers

link it to both these structures and to its fellow of the opposite side. It receives fibers from, and sends a few fibers to the globus pallidus (p. 874).

THE EFFECTS OF EXPERIMENTAL STIMULATION AND INJURY OF THE BASAL GANGLIA

Phasic movements in any way like those which can be elicited by excitation of the motor cortex cannot be induced by stimulation of the basal ganglia or of the subthalamic region. When such movements occur they are attributed to the escape of current to the internal capsule. The slow movement of the legs of cats was observed by Miller upon unipolar faradization of the caudate nucleus or by the application of warm water or of strychnine, which appears to be due to the excitation of this nucleus itself. The outstanding result of stimulation of the striate body is observed during muscular movements initiated from the motor cortex or when the limbs are held by tonic postural contractions; then inhibition promptly occurs. Among the most definite experimental results are those of Mettler and his associates. They observed the following effects of electrical stimulation of the corpus striatum in monkeys. (a) Movements induced by excitation of the motor cortex were inhibited by concurrent stimulation of the caudate nucleus, putamen or claustrum; (b) stimulation of the globus pallidus added to movements initiated from the motor cortex, an element of "plastic tonus" which exerted a "holding" action upon the movements and prolonged their reaction time.

Experimental lesions of the striatal region in dogs or cats result in no noticeable motor defect and in monkeys is any pronounced effect observed. Kinnier Wilson found that when extensive unilateral lesions were made the animals used a preference for the arm and hand of the ipsilateral side and showed clumsiness of movement on the limb of the opposite side. There was, however, no paralysis or even paresis. In chimpanzees striatal injury is followed by athetoid movements (p. 878) closely similar to those seen in persons suffering from disease of this region. Brown observed tremors in monkeys following large bilateral lesions in the putamen or smaller bilateral lesions of the globus pallidus. Liddell and Phillips observed slight but persistent hypertonus in the extensor muscles of the opposite side and flexor hypertonus on the same side following electrolytic lesions in the corpus striatum. Placing reactions were imperfect and closure of the contralateral

eral eyelid was defective. The highest integrative level of the corticostriatonigral system consists of cells in areas 6 and 4 and especially in the strip of cortex (4; or "strip area of Hines") lying between these areas.

FUNCTIONS OF THE EXTRAPYRAMIDAL SYSTEM

The corpus striatum is one of the oldest parts of the cerebrum, and the globus pallidus (*paleostriatum*) is older phylogenetically than the putamencaudate portion (*neostriatum*). The connections of the paleostriatum are chiefly efferent; the neostriatum is mainly receptive. In lower vertebrates (e.g., fishes, amphibia, reptiles and birds), in which the cortical mantle is absent or rudimentary and the pyramidal system has not yet come into being, the corpus striatum¹ is the highest motor center, being looked upon as homologous with the motor cortex of higher forms. Upon this "old motor center" and its connections with lower levels very largely depend the motor activities of submammalian forms. In the bird, for instance, after removal of its rudimentary cortex, visual and auditory sensations seem unaffected and it continues to carry out normal movements of feeding, courting, fighting, etc. These instinctive reactions are imperfectly executed after removal of portions of the striate body. With the evolution of the cortex and the arrival of the pyramidal tracts (in mammals) the functions of the extrapyramidal system though subordinated to those of the motor cortex are not lost but, on the contrary, carry out those more or less automatic or reflex movements concerned with the maintenance of posture, defence, feeding, etc. In the cat or dog for example almost normal activities can be executed after destruction of the pyramidal system (by removal of the cortex). The extrapyramidal paths undoubtedly play an important rôle in the ordinary motor activities of these animals. In man the cortical representation of the extrapyramidal system is probably in the premotor area (p. 888). Wilson's view of the functions of this system in the human subject is that through the convergence of its paths upon the spinal motor neurons it maintains a postural background against which voluntary movements are executed. Impulses traveling these paths exert, he believes, a steadying

effect upon, but do not themselves initiate, such movements. Kappers, however, considers that the habitual or automatic acts of daily life are mediated through this extrapyramidal system and points out that such types of movement suffer the greatest impairment in striatal disease.

CLINICAL MANIFESTATIONS OF DISEASE OF THE EXTRAPYRAMIDAL SYSTEM

The chief clinical features of extrapyramidal disease are: (a) muscular rigidity resulting in disturbances of posture and movement, (b) involuntary movements, e.g., tremor, athetosis, chorea. (c) absence of any true paralysis. The corpus striatum and other parts of the extrapyramidal system seem to be peculiarly susceptible to the actions of certain toxic substances. The following are some of the syndromes met with: (1) *Progressive hepato-lenticular degeneration*, (2) *Parkinsonism*—paralysis agitans, etc., (3) *chorea*, (4) *athetosis*, (5) *tortion spasm*.

HEPATO-LENTICULAR DEGENERATION (WILSON'S DISEASE)

This was described by Wilson in 1912. It invariably terminates fatally but its duration varies from a few months to several years. The following are its chief features:

(a) *Muscular rigidity* is wide spread and progressive; it involves face, trunk and limbs. Flexors as well as extensors are affected, but the former more conspicuously than the latter. The hypertonus offers a "lead-pipe-like" resistance to passive movement and results in slowness and difficulty of movement. Eventually, the patient is rendered almost immobile as though carved from stone; he can be lifted or moved *en bloc*. The rigidity of the facial muscles gives a fixed, immobile expression. The mouth is sometimes held widely open; the smile or laugh is peculiarly stiff and vacuous. The hypertonus of the muscles of articulation and deglutition leads to dysarthria (p. 899) and dysphagia. The rigidity is temporarily abolished by the injection of novocaine into the muscles and therefore dependent upon afferent impulses.

(b) *Involuntary movements*. These consist chiefly of tremor (about 6 oscillations per sec.) which is increased by excitement or any attempt at voluntary movement; sometimes athetoid movements (p. 878) occur.

(c) *The reflexes are normal*. There are no sensory changes and although the muscles often show some weakness and are easily fatigued there is no actual paralysis.

(d) *Cirrhosis (multilobular) of the liver* is found at autopsy, but during life there may be no signs of liver disease. In some instances, however, symptoms pointing to the liver precede the nervous manifestations.

¹ The infant's movements are of such a nature as to suggest that they are under the control of the extrapyramidal system, the pyramidal system being as yet not fully developed.

(e) *Emotionalism*. Involuntary laughing or crying, and some mental deterioration.

(f) *Greenish brown pigmentation of the cornea (in Descemet's membrane) occurs in a proportion of cases.*

Degeneration of the cells of the putamen and sometimes cavity formation are found at autopsy. The caudate nucleus and globus pallidus are affected to a much less degree. A toxin of some sort is probably responsible for the disease. It is possible that the toxic substance is absorbed from the alimentary canal, and damages both hepatic and nervous tissue.

THE PARKINSONIAN SYNDROME

The principle features of this syndrome are the following: (a) A *coarse tremor* involving head and limbs. The hand may show pill-rolling movements, i.e., rhythmical movements of thumb upon the first two fingers; alternating movements of flexion and extension at the wrist, or of supination and pronation of the forearm, are frequently present. When the limb is engaged in some voluntary act the movements often temporarily disappear in that limb but become more pronounced in other parts. (b) *Muscular rigidity* which leads to slowness and stiffness of movement and a fixed mask-like expression (Parkinson's mask); the patient winks infrequently, and speech is slow. The upper limbs are held in characteristic attitudes of adduction at the shoulders, flexion at the elbows, flexion or slight extension at the wrists, flexion at the metacarpophalangeal joints and slight flexion at the interphalangeal joints. (c) The *gait* is slow and shuffling with short steps, or it may be "festinating" in character, i.e., the patient is bent forward and hastens along with short quick steps as though trying to "catch up to his center of gravity" and prevent his falling. When pushed forward or backward he cannot stop quickly but moves by a series of small rapidly repeated steps in the direction in which he is pushed. *Propulsion* and *retropulsion* are the respective terms applied to these forward and backward movements. There is no true paralysis; the reflexes and sensation are unaffected. The condition is due to degenerative changes in the corpus striatum; according to Hunt, the chief lesion is a progressive atrophy of the globus pallidus. Degeneration of the muscle spindles also occurs.

The picture of Parkinsonism just drawn is one which is seen in elderly persons; it occurs without apparent cause and is slowly progressive. It is also spoken of as *paralysis agitans*. Other forms of Parkinsonism, essentially the same in their manifestations but differing in detail may

occur at any age and develop more rapidly as result of *epidemic encephalitis* (encephalitis lethargica). Rigidity is the most prominent feature of the post-encephalitic type—choreic and athetoid movements may also occur. The patient may assume statuesque attitudes for long periods—*catatonia*—or maintain the limb in a position which has been passively imposed upon it. The substantia nigra is particularly chosen for attack in this type. The locus coeruleus in the floor of the 4th ventricle is also affected in a proportion of cases, and this fact may account for the disturbances in the autonomic nervous system which is sometimes a prominent feature (McAlpine). Trauma and poisoning by carbon monoxide or manganese are unusual causes of Parkinsonism. It may also result from cerebral arteriosclerosis.

ATHETOSIS (MOBILE SPASM)

This is the term applied to movements of a peculiar slow writhing, twisting or squirming character involving the upper limbs and less commonly the face and lower limbs. They may be unilateral or bilateral. They are increased when any voluntary movement is attempted but disappear during sleep. The muscles when not actually engaged in the abnormal movement are hypotonic. As seen in the hand the movement consists of alternate extension and flexion at the wrist and metacarpophalangeal joints, with the fingers usually held extended at the interphalangeal articulations. Involvement of the facial muscles results in grotesque facial expressions (grimacing); involvement of the muscles of the mouth and throat causes disturbances of articulation and of deglutition.

Though athetoid movements occur in lesions of the pyramidal paths the presence of some intact pyramidal fibers has been considered to be essential for their occurrence; the movements are abolished if as a result of subsequent lesion the pyramidal pathway is completely interrupted. For example, extirpation of, or the injection of alcohol into, the motor area of the cortex governing the muscles involved prevents the movements. Wilson believes that the abnormality is due to degeneration of the cerebello-rubrothalamo-cortical pathway and the release of the pyramidal system from a controlling influence. The following observation suggests, however, that the impulses giving rise to the movements travel over extrapyramidal paths (from motor area via the striate body to spinal centers).

(a) Division of the anterior columns of the cord (which, through the reticulospinal tracts, are believed to transmit striatal impulses) in a subject of athetosis abolished all abnormal movements below the section level, but left voluntary (pyramidal) innervation unimpaired.

(b) Bucy and Buchanan have reported the case

a child whose athetoid movements were abolished permanently by the excision of the central part of the precentral gyrus (i.e., area 6a α of the premotor cortex, p. 888) leaving the motor area almost intact. These observers suggest that the movements are due to a hyperexcitable state of area 6a α , and that their cessation, following injury to the pyramidal tracts, is in reality due to the interruption of the connections of this area with the motor cortex (area 4).

(c) Lesions in the striate body, substantia nigra or body of Luys have been found at autopsy in cases which had shown athetosis. It also occurs in conditions such as cerebral diplegia, in which the premotor as well as the motor area is frequently injured.

CHOREA

There are two principal forms of this condition.

(1) **SYDENHAM'S CHOREA** (or St. Vitus's dance) is not uncommonly a sequel to acute rheumatism. Its chief features are: (a) involuntary jerky movements, semi-purposeful in character, involving the muscles of the limbs and face. They are intensified by excitement but disappear during sleep. The mobility of the face is in marked contrast to the fixed "starched" expression of Parkinsonism. There may be athetoid movements, the condition then being termed *atheto-chorea*. (b) Hypotonia of the muscles.

Sydenham's chorea may be bilateral or unilateral (hemichorea). Death is rare and there is consequently uncertainty concerning its neuropathology. The lesions are probably similar in nature to those responsible for athetosis. Degenerative changes in the corpus striatum (chiefly in the putamen and caudate nucleus), substantia nigra and body of Luys have been described in fatal cases. Hemorrhage into the body of Luys of one side has been found in hemichorea.

(2) **HUNTINGTON'S CHOREA** is a much more serious affection, being usually fatal. It is hereditary, showing Mendelian dominance. Of about 1000 cases arising in the United States practically all can be traced to some half dozen individuals, including three brothers who settled there in the 17th century. The choreiform movements are often violent; there are dysarthria, ataxia of the limbs and progressive dementia. The changes in the central nervous system are, marked atrophy of the cerebral cortex and the corpus striatum. Of the latter, the putamen and caudate nucleus are involved; the globus pallidus escapes.

Tortion spasm is a very rare condition and need only be defined. It consists of spasms of neck, trunk and limb muscles which twist the body into bizarre attitudes. The muscles, following the spasm, are hypotonic. Pathological changes in various parts of the extrapyramidal system have been described.

THE THALAMUS

This large gray mass is related medially to the 3rd ventricle which lies between the thalami of the two

sides. The posterior limb of the internal capsule lies upon the outer side of the thalamus and separates it from the lentiform nucleus. Above the thalamus is the lateral ventricle, a part of whose floor it forms. In front is the head of the caudate nucleus; the arched body of the latter is related to the upper part of the lateral surface of the thalamus. Below the thalamus are the red nucleus, corpus of Luys and substantia nigra (subthalamic region). (Fig. 371.)

The thalamus contains five main nuclear groups, 1, *anterior*, 2, *ventral*, 3, *dorsomedial*, 4, *lateral* and 5, *nuclei of the mid-line*. The *anterior nuclei* form a mass which bulges into the lateral ventricle and consists of three distinct groups of cells, the *anterodorsal*, *anteroventral* and *anteromedial* nuclei. The anterior nuclei receive fibers from the mammillary bodies (mamillo-thalamic tract of Vicq d'Azyr) which convey olfactory impulses. They send fibers to the paracentral lobule and the cingular gyrus on the mesial aspect of hemisphere.

The *ventral nuclei* consist of two cell groups, the *lateroventral* and the *posteroventral* nuclei. The lateroventral nucleus receives fibers from the dentate nucleus of the cerebellum via the brachium conjunctiva and sends fibers to areas 4 and 6 of the cerebral cortex, the forepart of the nucleus being connected with the foot area of the cortex, the central part with the arm area, and the medial portion with the cortical area governing the facial muscles. The posteroventral nucleus is the main relay station for afferent impulses travelling to the cerebral cortex. It receives fibers from the spinothalamic tract, from the nuclei of the posterior columns and from the trigeminal nuclei. It sends fibers to the postcentral convolution.

The *dorsomedial nucleus*. This, like the lateral nucleus, is an association center. It is connected by many fibers with the lateral nucleus, and with the hypothalamus and the prefrontal area of the cerebral cortex.

The *lateral nucleus* consists of a *dorsal* and a *posterior* portion. The main connections of the dorsal part are with the ventral group of nuclei. The posterior part receives fibers from the dorsal region and from the tectum. Fibers connect it with the parietal cortex exclusive of the postcentral gyrus. The expansion of the posterior part of the lateral nucleus which overhangs the superior colliculus is known as the *pulvinar*. Cells in the inferior part of the nucleus send fibers to the cortex adjacent to the visual area (area 18) while the main part projects to the cortex adjacent to the auditory area.

Mid-line nuclei. These nuclei are situated in that part of the thalamus which forms the upper part of the wall of the third ventricle. They are connected by many fine myelinated fibers with subcortical centers, namely, the hypothalamus and mid-brain nuclei. They also receive fibers from the corpus striatum. These nuclei have many intrathalamic connections but few if any fibers connect them with the cerebral cortex.

It will be seen from the foregoing account that the nuclei of the thalamus can be divided upon a functional basis into three categories, namely, (a) those which serve as relay stations of afferent impulses from the periphery to the cortex, (b) those which are connected mainly with subcortical centers and (c) those whose chief function is associative.

The thalamus (which portion is undecided) also sends fibers to the olivary nucleus (*thalamo-olivary tract*).

Functions

We have seen that the corpus striatum represents the highest level of an old motor system. The thalamus, on the other hand, is a primitive receptive center wherein sensory impulses give rise to a *crude uncritical form of consciousness*. It serves as a great integrating center; through its connections with the corpus striatum, tactile, painful, olfactory and gustatory impulses are correlated with motor reactions. Sensory localization in the thalamus has been demonstrated by Dusser de Barenne and Sager by means of local strychninization. The injection of a minute quantity of the drug into the thalamus in cats is followed by hyperesthesia and hyperalgesia to cutaneous and deep (muscle, tendon and periosteum) stimuli. The cutaneous hypersensitivity is most pronounced on the contralateral side of the body; increased sensitivity to deep stimuli occurs only on the contralateral side. By this method, *sensory areas in the lateral nucleus* of the thalamus for the head, arm and leg have been located. These areas are not, however, sharply delineated as in the cerebral cortex but show rather wide overlapping.

The thalamus is not, however, entirely sensory in function. In animals possessed of little or no cortex, or in higher mammals (e.g., cat or dog) after decortication, it and the corpus striatum serve for the execution of complex movements of an automatic or reflex nature. Motor responses also result from its direction stimulation. Conjugate deviation of the head and eyes to the opposite side and movements of progression in the limbs follow electrical excitation of the ventral nucleus. The pulvinar has in the past been looked upon as a relay station in the transmission of visual impulses to the occipital cortex. It now appears, however, from the researches of Brouwer and Zeeman that though this part of the thalamus receives fibers of the optic tract, it is not a primary visual center (see p. 1008).

The regrouping of afferent impulses within the thalamus

The clinical researches of Head and Holmes indicate that the various types of sensory impulse which reach the lateral nucleus are regrouped. The cruder, more essentially primitive sensation (protopathic), e.g., *pain, extremes of temperature, pressure, and contact* over hair-clad parts are relayed to and terminate in what has been called by Head and Holmes "the essential organ of the thalamus." This probably corresponds to the medial nucleus. Impulses arriving in the "essential organ" arouse a type of consciousness or "crude awareness" in which the character of the sensations comes under the category of "feelings (affective sensations), both pleasurable and disagreeable. They are devoid of discriminative qualities. Fibers subserving the finer discriminative sensations are relayed from the lateral nucleus of the thalamus to the somaesthetic area of the cortex (fig. 373). These latter fibers ascend through the posterior limb of the internal capsule (thalamic radiation) and apparently are in five groups, mediating respectively the following sensations:

- (a) Light touch to hairless parts.
- (b) Localization of the point touched.
- (c) Spatial discrimination.
- (d) Temperatures between 25° and 40°.
- (e) Position and passive movements of the limbs.

Thalamic lesions

The effects resulting from a lesion involving the lateral thalamic nucleus will resemble those following an interruption of ascending pathways in the brain stem above their decussation. That is, all types of sensation on the opposite side of the body tend to be lost or grossly affected, or there may be severe pain as a result of destruction of inhibitory mechanisms or possibly of the direct stimulation (irritation) of pain fibers. A lesion involving the fibers after regrouping (i.e., after the epicritic types of sensation have been sorted from the cruder sensations and are ascending to the cortex) will cause a loss of the discriminative types of sensation alone. A lesion in the internal capsule (thalamic radiation) or corona radiata might have such an effect (see pp. 862, 863).

THE THALAMIC SYNDROME ("SYNDROME THALAMIQUE") OF DÉJERINE AND ROUSSY. This is

characteristic picture occasionally seen in thalamic disease. The following are its chief features:

(1) Astereognosis and slight ataxia, due to the loss of the sense of position. These and the other effects given below are of course on the side of the body opposite to that of the lesion.

(2) Some loss of tactile and thermal sensations over the body and face. The threshold for pain is frequently raised. The loss of sensation is variable both in degree and type, depending upon

FIG. 373. Diagram showing the paths and centers concerned in sensation. All sensory impulses ascend to the lateral part of the thalamus, where regrouping occurs; the cruder sensations (e.g., those of pain and extremes of temperature) are relayed to the medial portion of the thalamus, the remainder (e.g., light touch, discrimination of two points, sense of position and movement, etc.) to the cerebral cortex. The corticothalamic fibers, which terminate in the lateral nucleus of the thalamus are also shown (after Head).

the extent of the lesion. In some instances the sensory loss is slight.

(3) Spontaneous pain occurring in paroxysms and often excruciating in character. The pain may be so intense as to resist the action of powerful sedatives, e.g., morphine. A painful stimulus is felt much more acutely than is normal (hyperaesthesia); and though, as mentioned above, the threshold for pain is often raised, the sensation when once aroused (by increasing the strength

of stimulus) is excessively severe. The spontaneous pain and the magnification of the response to painful stimuli are usually referred to as the *thalamic over-reaction*.

The over-reaction phenomena are due, according to Head and Holmes, to the release of the "essential organ of the thalamus" from the restraining influence which the cortex exerts normally through the corticothalamic fibers. The symptoms are the result of a lesion involving these fibers or their connections in the lateral part of the lateral nucleus of the thalamus.³ But the sensory disturbances just described are not associated exclusively with thalamic lesions; they may also be caused by disease of the brainstem, spinal cord or even of the peripheral nerves. Kendall has offered an explanation for the disturbances of sensation, especially of the over-reaction on the basis of the existence of two central pathways for pain—a rapidly conducting and a slowly conducting system of fibers, the former exerting an inhibitory influence upon the latter. Interruption of the fibers of rapid conduction, which are thought to transmit the epicritic sensations, would account for the blunting of tactile and thermal perception and would allow a greater response of the slowly conducting system over which, it is suggested, protopathic sensations are transmitted. Kendall draws attention to a familiar experience, namely, the more intensely painful sensation which follows a little time after the immediate response to a painful stimulus. The delayed sensation, which is most commonly felt when the skin comes into contact with a very hot object, appears to be similar in quality to that described as being characteristic of the thalamic syndrome (see p. 802). The thalamic syndrome includes other unpleasant sensations; even a form of stimulation, such as tickling the sole of the foot, which produces no discomfort on the sound side, is highly unpleasant on the other side. Many patients complain that shaving the affected side of the face feels as if the razor were being drawn over a raw surface. Even cutting the hair or nails may be objected to as being extremely disagreeable.

Sensations of pleasure are also increased in intensity. Warmth applied to the skin may cause the keenest en-

³ The persistence of a long period of the phenomena of over-reaction together with the exaggerated sensations of pleasure argue against their being simply due to the irritation of sensory paths. It is also doubtful whether the pain is truly spontaneous; it is more probably the result of some mild but undetermined stimulus

joyment and evoke such expressions as "exquisite," "lovely," etc. The patient, however, may be quite unable to appreciate that the sensation is one of warmth. During emotion disagreeable sensations occur on the affected side. Thus one of Head's patients was so affected by music that "he could not stand the hymns on his affected side," another said that when the choir sang "a horrid feeling came on the affected side and the leg . . . started to shake." In another patient pleasant feelings of a psychic nature were referred to the abnormal side. He said "I seem to crave for sympathy on my right side," and "My right hand seems to be more artistic."

THE HYPOTHALAMUS

The hypothalamus is the basal part of the diencephalon (interbrain). It lies in relation to

FIG. 374. The hypothalamic nuclei and connections. A.C., anterior commissure; Ch., optic chiasma; M.B., mammillary bodies. Nuclei; 1, paraventricular; 2, supraoptic; 3, tuber cinereum; 4, posterior hypothalamic.

the floor and lower parts of the walls of the 3rd ventricle (fig. 374). From a strictly anatomical point of view it may be taken to include the following structures: (a) *optic chiasma*, (b) *tuber cinereum* and the other nuclear masses in relation to the floor and ventral parts of the walls of the 3rd ventricle, (c) the *pituitary gland*, (d) the *corpora mammillaria* and (e) the *subthalamus* (p. 876). In physiological literature the term has usually a more restricted connotation including only (b) and (d) (see also p. 722).

Of the *nuclei of the hypothalamus* the greatest interest from the physiological point of view centers around the following.

The *supraoptic nucleus* lies above the optic chiasma and the commencement of the optic tract of the corresponding side. The *paraventricular nucleus* is situated above the supraoptic nucleus and is in close relationship medially to the wall of the 3rd ventricle and laterally to the column of the fornix. The *posterior hypothalamic nucleus* lies in the posterior part of the hypothalamus in relation to the wall of the 3rd ventricle; it extends backwards over the mammillary region. The *tuber cinereum* is a small eminence of gray matter

situated at the base of the brain between the optic chiasma and the mammillary bodies, i.e., in the posterior region of the hypothalamus. Out of it grows the pituitary stalk. Two groups of cells can be clearly defined within it; they are known as the *dorsomedial* and *ventromedial hypothalamic nuclei*.

Fiber connections. The hypothalamus receives fibers from the thalamus, and through the *medial forebrain bundle*, from the olfactory lobe and the parolfactory area. The medial forebrain bundle sweeps through the hypothalamus and in its course gives off fibers to several of the hypothalamic nuclei. It has been suggested on the basis of physiological experiments that a direct connection exists between the cortex and the hypothalamus, but such has not been demonstrated histologically. There seems little doubt, however, that a part of the brain is in communication with the cerebral cortex through indirect paths, e.g., through the thalamus. Efferent tracts descend from the hypothalamus through the midbrain and probably to the spinal cord. The various hypothalamic nuclei are in communication with one another through fiber tracts; the best known of these is the paraventricular-supraoptic tract, but others undoubtedly exist.

The supraoptic, paraventricular and tuberal nuclei are linked with the hypophysis by efferent fibers which descend the infundibular stalk (hypothalamo-hypophyseal tract). The majority of these fibers terminate around the pituicytes of the pars nervosa but some can be traced into the pars intermedia and the pars anterior (p. 1214).

THE PHYSIOLOGY OF THE HYPOTHALAMIC NUCLEI

Recent experimental and clinical investigations have revealed the hypothalamus as a region of great physiological importance. Our knowledge of the functions of this part of the cerebrum is still, nevertheless, very incomplete. Much of the evidence is suggestive rather than conclusive and permits only tentative views to be held concerning many of its activities. It is the general opinion, however, that in this part of the diencephalon are contained the mechanisms for the control of certain primitive reactions (visceral and somatic) associated in animals with defence, attack, and in man with emotional states (fear, anger, etc.). This region is also believed to contain centers for the regulation of certain fundamental and vital processes, e.g., fat, carbohydrate and water metabolism, and to exert a governing influence upon the body temperature, the gas movements, the genital functions and the sleep rhythm (p. 918).

It is now generally conceded that important centers governing the activities of the autonomic nervous system are situated in the hypothalamus.

Those cell groups in the anterior part of the hypothalamus and in the tuberal region are believed to constitute a parasympathetic center, whereas from the posterior part a directing influence is exerted over sympathetic functions.

The pituitary and the nervous structures of the hypothalamus are intimately associated in function; indeed, they should be considered together as constituting a closely integrated neuro-glandular mechanism rather than as possessing distinct and independent functions. It will be recalled that the pars nervosa of the pituitary is developed as a downgrowth from the floor of the 3rd ventricle, and that the pituicytes are modified neuroglial cells. On the other hand, the cells of the supraoptic and paraventricular nuclei of the hypothalamus show evidence of secretory activity. They have not the appearance of typical nerve cells for they contain granules resembling those found in glandular cells and droplets or larger collections of a colloid material can be observed within their cytoplasm; they also show vacuole formation which is rarely encountered in nerve cells. The rich vascular network which surrounds the cells of these nuclei, capillaries in some instances actually penetrating their protoplasm, strongly suggests a glandular function.

A brief summary of the experimental evidence relating to hypothalamic functions will be given in the following paragraphs.

(1) Karplus and Kreidl were the first to furnish evidence of a sympathetic center in the hypothalamus. Upon electrical stimulation of this region they obtained pupillary dilatation, sweating and a rise in blood pressure. Inhibition of intestinal movements also results. Liberation of adrenaline has also been reported to follow stimulation of the hypothalamus. By means of needle electrodes inserted into the region of the lateral nucleus Bronk and his colleagues have recorded impulses from sympathetic efferent nerves during stimulation of the hypothalamus. On the other hand, rhythmical variations in potential were produced in the hypothalamus by the stimulation of certain afferent nerves through which reflex sympathetic responses may be elicited.

(2) Beattie, Brow and Long found that extrasystoles produced in the cat by means of chloroform anesthesia, and which had been shown by Levy to be dependent upon sympathetic impulses (p. 198), were abolished by a destructive lesion placed in the posterior hypothalamic nuclei or by section of the brain behind this region. Stimulation of the posterior hypothalamic region, on

the other hand, caused extrasystoles to appear in an animal which previously had been free from these cardiac irregularities. Animals subjected to such lesions also showed hyperglycemia and glycosuria. Drowsiness for two or three days following the operation was a noticeable feature in some animals; they also showed a change in behavior, being more docile and "tamer" after the operation (see "sham rage" below). The nervous system of animals examined histologically some time after the lesions in the posterior hypothalamic nuclei had been made showed degenerating fibers which entered the mid-brain and descended through the brain stem and cord. Those in the latter situation entered the lateral column of gray matter at different levels down to the 3rd or 4th lumbar segment.

(3) Decerebration by a section through the mid-brain causes a profound fall in body temperature. No such loss of temperature control follows the removal of the cerebral cortex and thalamus, provided that the hypothalamus is left intact. It is significant that sympathetic effects, e.g., adrenaline liberation, ruffling of feathers or hairs, constriction of vessels and goose flesh, result from exposure to cold. Moreover, Cushing calls attention to the high temperature which frequently follows operations upon tumors in the region of the 3rd ventricle (see also p. 630).

(4) Hess fixed electrodes in the hypothalamus of cats. After the animals had recovered from the operation, a weak electric current passed through the hypothalamus induced a state indistinguishable from normal sleep. He also states that ergotoxin injected directly into the hypothalamic region induces sleep. This observation is, however, difficult to reconcile with the fact mentioned below that the intravenous injection of ergotoxin produces sham rage. Sham rage and other manifestations characteristic of hypothalamic stimulation also follow the local injection of a minute amount of strychnine.

(5) Kabat and associates by means of an electrode fixed in the hypothalamus stimulated this region in the unanesthetized animal. Pupillary dilatation, erection of hair, inhibition of gastrointestinal peristalsis, clawing and urination resulted. Stimulation of other parts of the brain produced none of these effects.

(6) The production of gastric lesions by hypothalamic injury and of ovulation by stimulation of the hypothalamus or of the hypothalamo-hypophyseal nerve tracts have been mentioned (pp. 446 and 756). Evidence for the control of

gastric motility by the hypothalamus has been cited on page 489.

Quasi-emotional state—"sham rage"

It was first demonstrated by Goltz that the reactions which usually accompany displeasure and anger are more readily evoked in an animal deprived of its cerebral cortex (decorticated) than in the normal animal. In Goltz's classical experiment the hemispheres and a large part of the thalamus were removed from a dog. The disposition of the animal was greatly altered by the operation, it being very readily aroused to anger. Barking, growling, baring the teeth or snapping occurred upon the least provocation. Cannon and Britton produced a similar state in cats by removal of the cortex, the decortication being performed by means of a pointed stilet inserted through the orbital cavities. Immediately following recovery from the anesthetic the animals showed the following remarkable phenomena which these observers termed "sham rage";—lashing of the tail, erection of the hairs, protrusion of the claws, dilatation of the pupils, sweating, struggling and biting, greatly increased rate of respiration and a rise in blood pressure. Most of these manifestations will be recognized as being of sympathetic origin. In many instances the picture is a combination of fear and anger. Liberation of adrenaline, as indicated by an increase in the rate of the denervated heart (p. 690), also occurred. The mildest stimulus such as jarring the table or lightly touching the animal was sufficient to evoke a paroxysm of rage. In his decortication experiments Bard found that the posterior and ventral portion of the diencephalon was essentially responsible for the development of "sham rage." The typical quasi-emotional behavior occurred after decortication and section through the hypothalamus at about the middle of the tuber cinereum. It also resulted from an operation which removed the corpora striata and the dorsal half of the diencephalon, i.e., the thalamus, but left the hypothalamus connected with the mid-brain. The condition failed to appear if the section separated the caudal part of the hypothalamus, i.e., the portion containing the posterior group of hypothalamic nuclei (p. 882), from the mid-brain. Taking the results of decortication experiments as a whole, one is led to the conclusion that the activities of the hypothalamus are normally under inhibitory influences from the cerebral cortex and that "sham rage" is the result of the release of these primitive subcortical centers from

higher control. Fulton and Ingraham, for instance, found that in order for the typical behavior to ensue decortication is unnecessary. Bilateral incision of the medial surface of the cerebral hemisphere in front of the optic chiasma is sufficient to produce hypothalamic over-reaction. Typical "sham rage" can be produced in intact cats by the intravenous injection of ergotoxin. It has been suggested that certain conditions in man, e.g., the manifestations of fear in shell-shock, the unreasoning rage of drunkenness, and the emotional instability of certain mental derangements associated with degenerative changes in the cortex may be due to the release of the hypothalamus from cortical control.

The evidence provided by the observations of Cushing and of Penfield for the existence of a parasympathetic center in the hypothalamus (p. 735) and the influence of this part of the brain upon water (p. 739), fat (p. 741) and carbohydrate metabolism (p. 593) are considered elsewhere.

DISORDERS OF THE HYPOTHALAMUS

The effects which may result from lesion (e.g., tumors, encephalitis, etc.) involving the hypothalamic region fall into the following groups: (a) disturbances in fat, carbohydrate or water metabolism (p. 739), (b) disorders of sleep, drowsiness, somnolence and, less commonly abnormal wakefulness, or reversal of the sleep rhythm,³ (c) emotional manifestations, laughing, crying, or a state resembling "sham rage" in animals, may result, (d) phenomena attributable to sympathetic or parasympathetic stimulation (e) disorders of the sexual functions.

Any one of the foregoing groups of effects may dominate the clinical condition to give rise to one or other of the following syndromes:

- (a) Diabetes insipidus.
- (b) Dystrophia adiposo-genitalis.
- (c) Laurence-Biedl-Moon syndrome.
- (d) Autonomic diencephalic epilepsy.
- (e) Narcolepsy.

These several conditions, with the exception of the last (e), have already been considered in the chapter devoted to the pituitary gland.

Narcolepsy (see also p. 918)

This is the term applied to a disturbance in the sleep mechanism in which sudden attacks of an irresistible desire for sleep occur during the day-time. The dura-

³ See Fulton and Bremer.

tion of the attacks, which resemble normal sleep, is quite brief—from a few seconds to 20 minutes or so. It is only to such sudden and brief naps, and not to persistent drowsiness or to prolonged periods of pathological sleep that the term is applicable. Nocturnal sleep may be normal but it is often disturbed or there may be insomnia. Sleep may overcome the subject of narcolepsy while he is going about his usual occupation, while walking, in the middle of a conversation, during a meal, driving a car, etc. There may be many attacks during the day. A few cases were discovered during the war in soldiers under trial by court-martial for falling asleep on sentry duty. The condition may be a sequel to influenza or to epidemic encephalitis involving the hypothalamus or may result from a tumor in this region. In other instances the condition follows a head injury or appears without known cause (idiopathic narcolepsy). Though evidence is not conclusive, it is very likely that in these latter, also, disordered hypothalamic function is responsible, for other features, e.g., obesity, polyuria or impairment of the sexual functions, pointing to an abnormality of this region are frequently present. *Ephedrine sulphate* (25 mgm. three times daily) or *benzedrine* is used with benefit in idiopathic narcolepsy. *Cataplexy*⁴ is the term given to a condition allied to, and very frequently associated with narcolepsy, in which the patient as a result of some emotion—amusement, anger, fear, embarrassment or surprise—is seized with complete helplessness. The attack

is brief, lasting for a few seconds, or for a minute or two at the most. Consciousness is not lost but the muscles are completely toneless and powerless for the time, and if the subject is attacked while standing his knees fail him and he sinks to the ground. The deep reflexes are lost. A normal person may become "weak with laughter," be "struck all of a heap," or "transfixed" when surprised or shocked. Or his jaw may "drop" when confronted with some unexpected occurrence. Cataplexy is regarded as an exaggeration of this normal tendency, just as narcolepsy is an intensification of the desire of many normal persons to drop into a doze under certain circumstances. Mirth is especially likely to precipitate a cataplectic attack. One victim reported by Adie remarked, "at the scout's camp the boys used to amuse themselves by making me laugh and then running away leaving me helpless on the ground." Even amusement without laughter will induce the helpless state in a susceptible subject, or it may ensue without apparent cause. Though narcolepsy occurs without cataplexy the reverse is extremely rare. This association of the two conditions at once suggests a common pathogenesis, but the muscular atonicity characterizing the cataplectic attack cannot be explained upon any physiological basis. An interesting speculation has been made by Wilson. By comparing the attacks to the defense reaction of certain animals whereby they fall into immobility when frightened, he suggests for them a certain biological significance, namely, that they are the relic of a primitive reaction uncovered by disease.

⁴ This should not be confused with catalepsy, an entirely different condition (p. 919).

CHAPTER LXIX

THE CEREBRAL CORTEX. THE PHYSIOLOGY OF SPEECH AND SOME OF ITS DISORDERS. APRAXIA AND AGNOSIA. EPILEPSY. HEADACHE

MINUTE STRUCTURE OF THE CORTEX

The human cerebral cortex has a total area of about 220,000 square millimeters; not more than a third of this lies upon the free surface or crown of the convolutions. The remaining two-thirds of the gray mantle of the cerebrum occupies the walls of the sulci. On the basis of cellular structure the major part of the cortical gray matter is divisible into *six layers or laminae*. These layers do not show identical histological appearances throughout the extent of the cortex. Characteristic differences in the depth of the individual layers and in their cellular components are found in the various regions. The six layers from the surface inwards with a general description of their cellular features as given by Economo¹ follows (see fig. 375).

I. MOLECULAR (OR PLEXIFORM LAYER). In this, the most superficial layer, the terminal filaments of numerous axons and dendrites form a dense felted network. Its cells are sparse; they are small (4 to 6 μ) and pear-shaped or fusiform.

II. EXTERNAL GRANULAR LAYER consists of large numbers of small round, polygonal or triangular cells closely packed together. Nerve fibers are scanty.

III. PYRAMIDAL CELL LAYER. Medium-sized pyramidal cells are contained in the outer part of this layer; pyramidal cells of larger size and more sparsely distributed are present in the deeper part. It is customary, therefore, to subdivide this layer into an outer and an inner portion; Campbell refers to them as separate layers.

IV. INTERNAL GRANULAR LAYER resembles the external granular layer, being composed of masses of small round granule-like cells. Unlike the external granular layer it is rich in medullated nerve fibers. Its depth is greatest in the calcarine cortex where it gives rise to the well-marked line of Gennari.

V. GANGLIONIC LAYER (or internal pyramidal layer) consists of pyramidal cells of graded sizes. This layer is particularly well-developed in the precentral (motor) cortex where giant pyramidal cells (Betz) are conspicuous. Its deeper strata contain a dense network of myelinated fibers.

VI. FUSIFORM CELL LAYER, in contact with the white matter, is composed of closely packed small spindle-

shaped cells which lie with their long diameters perpendicular.

It should be emphasized that the foregoing more than a general description of the histological structure of the cortex and that marked regional differences exist. Even the lamination itself is a feature common to the entire cortex. In one-twelfth of the cortical area shows little or no lamination; this portion, which is called the *isocortex*, comprises the cortex of the olfactory (i.e., the pyriform area and the hippocampal, supracallosal and olfactory gyri, etc.). The laminated cortex, which in man constitutes the remaining eleven-twelfths and in animals is a much smaller fraction of the whole, is called the *isocortex*.

Over the greater part of the frontal, occipital and temporal lobes the six layers show only minor regional peculiarities. Certain other regions possess distinctive features of a pronounced nature. In the cortex of the precentral gyrus, for instance, both granular layers (II and IV) are shallow, but encroached upon by the expansion of the pyramidal layers III and V. In the deep part of layer III this area are situated the characteristic giant cells of Betz (60 to 80 microns in their longest diameter) (see below). These cells give rise to the fibers composing the corticospinal (pyramidal) tracts. In the frontal cortex in front of the motor area (premotor and frontal association areas [9, 10, 11, and 12]) the granular layers are also inconspicuous but the cells of Betz are absent.

In the cortex of the walls of, and surrounding the calcarine fissure—the *area striata* or *visual cortex*—the departure from the typical histological picture is in the reverse direction. That is, the outer granular layers (II and IV) are expanded at the expense of the pyramidal layers (III and V). This *granular* type of cortex, also called from its “dusty” appearance under the microscope *koniocortex*, is characteristic of sensory areas. The *isocortex* is present, though to a less fully specialized degree than in the visual cortex, in the post-central gyrus and in Heschl's gyrus (auditory cortex, p. 8).

Upon gross examination of a section of the brain two lighter bands can be seen in the cortex again.

¹ For a detailed description, this author, or the earlier works of Campbell and of Bolton, should be consulted.

darker gray matter. These are produced by the fibers running parallel to the surface of the convolutions. They are known respectively as the outer and inner bands of Baillarger. In the precentral area the outer band is broad and prominent and is usually referred to as the band of Gennep.

THE FRONTAL LOBE

Area 4 lies in front of the central (Rolandic) fissure and comprises in man a variable extent of the precentral convolution. It contains the giant pyramidal cells of Betz which give rise to the corticospinal (pyramidal) tracts. It is the center for

Fig. 375. Area 4 of the human precentral region. Left, neuronal impregnation (Golgi); middle, Nissl cell stain; right, myelogenous stain. Note that the dendrites of the Betz cells (Vth layer) extend to the outer cortical layers (from Fulton after Brodmann).

of Vicq d'Azyr, who had described it previously. The inner band is absent in this area.

LOCALIZATION OF FUNCTION IN THE CEREBRAL CORTEX

Perster, following the numerical terminology of Brodmann and the Vogts, divides the cerebral cortex into several functional areas. Subordinate areas are indicated by letters. Only the more important of these areas will be given (see fig. 376).

voluntary movement, and for this reason is commonly referred to as the *motor area*. Electrical stimulation of parts of this area causes the movement of groups of muscles, different zones within it being correlated with definite muscle groups on the opposite side of the body. The movements induced by electrical stimulation are initiated in the fifth cortical layer and presumably in the giant pyramidal cells of Betz; destruction of the overlying layers by the method of thermo-coagulation

does not prevent the motor response (Dusser de Barenne). The cells controlling the muscles of the foot lie at the upper limit of the motor area. The area for the foot extends on to, or may be situated entirely upon the mesial surface of the hemisphere. Below the foot area lie, in order from above downwards, areas for the leg, thigh, trunk, shoulder, arm and hand. The area 6a α (see below) encroaches upon the center of the motor area dividing it into an upper and a lower half. Area 4 from above downwards controls, respectively, the mus-

possesses extrapyramidal projections (to striatum, etc.) and is in communication with the premotor area through intracortical connections.

Area 4s. This is a narrow band of cortex known as the "strip" area of Hines, lying between areas 4 and 6. Its cytology differs from area 4 in that the giant pyramidal cells of Betz are sparse and scattered. It is looked upon as transitional in cellular structure between areas 4 and 6. Electrical stimulation of this area causes inhibition of contractions of the limb muscles on the opposite

FIG. 376. Showing cortical areas (in part from Foerster and Penfield).

cles of the thumb, neck, face, tongue, jaw, palate and larynx (fig. 376). The representation in the motor cortex of parts such as the hands, lips, tongue and larynx that are capable of complicated or precise movements is much larger in extent relatively to the mass of muscle involved than is that of the neck, trunk, lower limbs, etc. The motor responses caused by the stimulation of area 4 are isolated or discrete in character, that is to say, with a suitably weak stimulus a movement involving a small group of muscles or even a single muscle can be evoked. Area 4, as well as projecting to the spinal cord (pyramidal or corticospinal tracts), also

side of the body; the threshold of excitation of area 4 is also raised.

Area 6 is that part of the cortex lying anterior to the precentral convolution from which complicated apparently purposeful movements of a more generalized type can be elicited by strong electric stimulation. Movements of a more discrete character, though never so discrete as those originating from area 4, can also be evoked from area 6 by weak stimulation during light anesthesia. Area 6 is divided into an upper and a lower part (areas 6a and 6b respectively, see diagram, fig. 376). Area 6a is now generally known as the *premotor area*.

it is subdivided into an upper and anterior and a lower and posterior portion. The former is designated area 6a α , the latter as area 6a β .

Area 6a β lies in front of the upper part of area 4. Its electrical stimulation results in movements which turn the eyes, head and trunk towards the opposite side (adversive movements) accompanied by movements of extension or of flexion of the contralateral limbs.

Area 6a α , as already mentioned, lies in man in the center of the precentral gyrus, splitting the motor area into an upper and lower region. In the monkey and ape the precentral gyrus is not divided in this way, the motor area (area 4) being continuous throughout the latter's extent. Faradic stimulation of area 6a α is followed by adversive movements similar to those arising from the stimulation of area 6a β .

Area 6b occupies the lower extremity of the precentral gyrus. Upon electrical stimulation coördinated rhythmical movements of the jaws, tongue, pharynx and larynx occur, resulting in licking, swallowing, grunting or hiccoughing.

These areas lying in front of the motor cortex differ physiologically from the latter in that the responses elicitable by electrical stimulation are usually of a more general and purposeful character, although as just mentioned movements of a more discrete character may also be evoked. They also require, as a rule, a much stronger stimulus for their excitation, a faradic current usually being necessary. Area 6b, however, can be excited by a galvanic current, and the rhythmical movements which result outlast the stimulus. The premotor area is believed to be a region wherein the synthesis of the more complicated voluntary movements and postural adjustments are carried out. It is therefore looked upon as the highest or third level of motor control, the motor area and the spinal centers representing, respectively, the second and first levels. (See page 890.)

The histology of the cortex of area 6 is similar to that of the motor area except for the important fact that the large pyramidal cells of Betz are absent from the fifth cortical layer. Smaller pyramidal cells, evidently motor in function, are seen in this layer. The fibers of area 6, therefore, are extrapyramidal. They descend through the anterior part of the internal capsule but their subcortical connections are far from being fully known; it seems clear, however, that fibers pass from the premotor area to the corpus striatum, red nucleus and the substantia nigra. The premotor area is therefore regarded as an important cortical center for

the corticostriatonigral system (p. 874). A few fibers, according to Hoff and Kennard, pass without interruption to the spinal centers in association with the pyramidal fibers. The premotor area also apparently gives rise to the frontopontine tract, and through this almost certainly projects to the cerebellum. Area 6b on the left side is intimately concerned with the mechanisms of speech.

Kinesthetic impulses are conveyed to areas 4, 4s and 6 from the lateroventral nucleus of the thalamus which receives them from the periphery via the spinocerebellar tract and cerebellum.

Area 8 occupies the posterior parts of the second and third frontal convolutions. Electrical stimulation of the upper part of this area causes a conjugate movement of the eyes to the opposite side (frontal eye field). If the stimulation is strong the head is turned in the same direction and the eye movements are jerking or clonic in character. Opening and closing of the lids, dilatation of the pupil and lacrimation of the opposite eye may also result.

The *prefrontal area* or *frontal association areas* (9, 10, 11 and 12) include all of the cortex lying anterior to areas 6 and 8. Areas 9 and 10 occupy the convexity and medial aspect of the frontal region, areas 10 and 11 its orbital aspect.

The results of extirpation of frontal areas

In lower vertebrates, e.g., fish, amphibia and birds, the rudimentary cortex plays a very subsidiary rôle in the control of motility. Subcortical and phylogenetically older portions of the cerebrum (corpus striatum and thalamus) are dominant (p. 874). The frog after cortical extirpation behaves in an almost normal fashion; and even the dog or cat walks a short time after the cortex has been removed, most of the postural reactions being retained (thalamic animal). The motor area of these animals is much less easily excited by electrical stimulation than is that of the monkey, ape or man, and the excitable area is much smaller in extent.

In monkeys, as shown by Lashley, destruction of the greater part of the precentral gyrus (motor area) does not abolish the animal's ability to perform acts previously learned, such as opening a hasped box to obtain food.

Fulton and Keller found that in the monkey after bilateral excision of the cortex of area 4 governing the lower limbs hip flexion was possible almost immediately after recovery from the anesthetic. Flaccid paralysis of the muscles of the knee, ankle, elbow and wrist persisted for three or four days,

but after this, voluntary power gradually returned, together with the tendon jerks. The proximally situated muscles recovered first. The finer movements of the digits returned slowly and incompletely. In the chimpanzee the results were similar but the loss of power was more profound and recovery slower. A positive Babinski without "fanning" of the toes was present. *In no instance was there permanent spasticity, which is usually considered in man to be due to a lesion of the motor area or corticospinal (pyramidal) pathway, observed after removal of the motor cortex alone.* Removal of area 6 or of area 4s ("strip" area), on the other hand, was followed by spasticity, increased tendon jerks, involuntary forced grasping and groping, and loss of the ability to execute complicated movements of the fingers. Rossolimo's sign (p. 873) and a positive Babinski, with fanning of the toes, appeared. Removal of the motor area on one side, followed by excision of the corresponding premotor area resulted in pronounced spasticity and loss of voluntary power in the contralateral limbs, accentuation of the Babinski response and fanning of the toes. The condition resembled the hemiplegia which in the human subject results from a lesion in the internal capsule. Fulton and his associates conclude that the sign of Babinski without fanning of the outer toes (p. 872) is indicative of a purely pyramidal lesion, the presence of the fanning component being an index of a premotor injury.

The connections of area 4 with the premotor area and with subcortical centers (corpus striatum, pons, etc.) render it impossible by means of a cortical lesion to produce effects attributable purely to the destruction of corticospinal projections. But the corticospinal fibers form two compact bundles—the pyramids—lying on the anterior aspect of the medulla (p. 862). Marshall and later Tower sectioned the pyramid of one side in cats and Tower and Hines in the monkey, thus accomplishing the dissociation of pyramidal from extrapyramidal effects. Section of the pyramid of one side in the medulla at the level of the trapezoid body resulted in paralysis of discrete movements of the opposite side, somewhat less in degree than that caused by ablation of area 4 itself. Larger movements (e.g., adverse) and, with strong stimulation, epileptiform responses were still elicitable. The most important finding was the absence of any sign of spasticity in the affected muscles, indeed there was some degree of hypotonicity (flaccidity). Ablation of area 4, especially of its anterior part, after pyramidal section increased the paralysis and induced hypertonus of the muscles. Stimulation of area 4

caused inhibition of the extensor tone of the paralyzed limbs, as well as of the sound (i.e., ipsilateral) limbs. Stimulation of area 6, on the other hand, induced hypotonicity of the flexor muscles, the grasp of the hand, for example, undergoing relaxation.

From the foregoing account of the various experimental results in this difficult field the following inferences may be drawn. (1) The pyramidal system (projections from area 4) governs the fine discrete or isolated motor responses, whereas the extrapyramidal system (projections from areas 4s, 4s and 6, but especially from the latter) are concerned with the larger coordinated responses (e.g., the so-called adverse movements). (2) Areas 4s and 6, particularly the latter, exert an inhibitory influence through extrapyramidal paths upon movements (mainly contralateral) governed through the pyramidal tracts. Extrapyramidal projections from areas 4s and 6 inhibit the tone of the flexors (e.g., relaxation of the grasp of the fingers); those from area 4 inhibit the extensors. (3) Pyramidal function includes as well a tonic action upon the spinal centers. Interruption of pyramidal pathways results in hypotonicity of the paralyzed muscles, whereas lesions of extrapyramidal paths cause spasticity. These conclusions have important clinical implications. The spastic state of the affected muscles in hemiplegia, for example, has been generally considered to be indicative of a destruction of pyramidal pathways. It appears, however, that interruption of extrapyramidal fibers, in their course through the internal capsule in close association with the corticospinal tracts, is responsible for the hypertonicity of the muscles. (4) The premotor area is capable of initiating certain relatively gross muscular acts quite independently of the motor cortex (area 4). Nevertheless, in the intact animal the two cortical regions are apparently closely correlated in function, the discrete movements of area 4 being integrated, through its connections with area 6, into the larger more complex movements involved in acts of skill and postural adjustments.

Fulton and his colleagues describe certain motor disorders in man which they consider to be characteristic of a lesion of the premotor area. These, which have been grouped under the term "*the syndrome of the premotor cortex*," are as follows: (a) awkwardness in the performance of delicate manual acts, e.g., buttoning a collar, sewing, etc., but little early loss of power in the execution of gross movements, (b) spasticity and increased tendon jerks, (c) forced grasping and groping (p. 892), late

appearance of weakness of the handgrasp and impairment of gross movements, and (d) autonomic disturbances. These effects are of course on the side of the body opposite to the lesion.

Unilateral excision of area 8 is followed in the monkey by conjugate deviation of the eyes to the side of the lesion and, during locomotion, rotation of the body to that side. A visual defect in the form of failure to recognize objects in the opposite monocular halves of the visual fields—a *pseudomianopia*—results. When area 8 is destroyed on both sides the animal does not react in a normal manner to visual stimuli. It may appear to be blind for it walks into or stumbles over obstructions in its path, and tends to stare straight ahead with an immobile “wooden” expression (see Kennard and Ectors). Yet, an animal will follow an object with its eyes and will seize anything offered to it though failing, apparently, to recognize it or to understand what to do with it.

Unilateral or bilateral removal of the *prefrontal* area (areas 9 and 10, 11 and 12), i.e., the portion of the frontal lobe lying in front of the premotor area causes no motor defect either in the monkey or man. Unilateral removal of the human prefrontal area is without any outstanding effect. The mental processes are impaired only to a minor extent. Some loss of initiative and mental alertness, and lowered ability for arithmetical calculations may be the sole result of the operation. Memory, judgment and intellect often show little or no deterioration. Removal of the prefrontal area of the dominant hemisphere (i.e., the left in right-handed and the right in left-handed persons) tends to produce somewhat greater alterations in character or intellect than does a similar operation on the non-dominant side. But even the bilateral excision of prefrontal areas is followed by surprisingly little mental defect. In an operation for the eradication of a tumor, Dandy excised the frontal lobes on both sides in front of the premotor areas (reported by Brickner). The subject of this extensive extirpation appeared of normal intelligence upon a casual acquaintance. It is reported that for an hour he toured the hospital with two visiting neurologists who failed to notice in him any mental abnormality. A more intimate knowledge of the patient, however, revealed very definite defects of character and mentality. His mental age was about thirteen years; his intelligence quotient eighty. The main features shown by this subject and which may be taken generally as representative of the effects of bilateral prefrontal destruction are as follows:

(1) *Lack of restraint* leading to boasting, self-aggrandizement, hostility, aggressiveness.

(2) *Distractibility*—difficulty in fixing attention.

(3) *Flight of ideas*, puerile fantasies, emotional instability, facetiousness, punning.

(4) *Lack of initiative*.

(5) *Impairment of memory* for recent events but not for remote events.

(6) *Impairment of moral and social sense*, loss of love for family.

(7) *Failure to realize*, or indifference to, the seriousness of his condition, and a sense of well-being (euphoria).

Among some of the other manifestations which may follow a prefrontal defect are: (a) increased appetite and loss of weight, (b) impaired control of the sphincter of the bladder or rectum, (c) disturbances of orientation in time and space, and (e) tremor.

Chimpanzees which have had both prefrontal areas (9, 10, 11 and 12) removed show restlessness and are easily distracted, though they remain alert and evince a keen interest in things around them. Jacobson has reported that after this operation the animals appear to be immune to experimental neurosis (p. 912) an observation which forms the basis for the surgical treatment of patients suffering from certain types of psychoneuroses namely, the severing of fibers connecting the frontal association areas with subcortical centers (probably the thalamus).

The frontal lobes and intelligence

The development of the frontal lobes bears in general a direct relationship to the level of an animal in the phylogenetic scale and to its intelligence. This has led to the belief that this part of the cerebrum is the seat of the intelligence of animals and the “center” or “organ” of the mind of man. Within this region those processes underlying intellectual, moral and emotional attributes were supposedly carried out. Extirpation experiments, however, show decisively that the prefrontal area cannot be looked upon as a region where these higher mental qualities reside exclusively. Intelligence depends upon a knowledge of the external world received through various channels. Visual, auditory, somesthetic perceptions, etc., are received and stored as memories in cortical areas situated in the occipital, temporal and parietal lobes. Tracts of association fibers link together in turn these several primary areas; sensations of various types are thereby brought into relationship, and synthesized into more complex memories.

Thus, as time passes, the fabric of our experience is woven in patterns of greater and greater intricacy.

It is probable that the prefrontal area merely represents a region of relatively high associative or synthetic capabilities. After its bilateral removal the cerebrum deprived of the synthesizing faculty of this region is incapable of the more elaborate association of those experiences required for the formulation of abstract ideas and more accurate judgment, and for the guidance of conduct in conformity with social customs. Nevertheless, synthesis at somewhat lower levels is still possible of achievement through the remaining cerebral tissue. Mental capacity according to this conception is therefore a function of the cerebral cortex as a whole rather than of any particular region. The *quantity* of tissue removed rather than its *location* is the more important factor in determining the degree of mental impairment which will result. (See Lashley.) It may be mentioned in this regard that the symptoms which are observed in prefrontal lesions can all be accounted for by a reduction in associative ability. Bolton has also shown that in amentia and dementia the degeneration of the cortical layers is not localized to any particular region but is distributed over the hemispheres.

THE CEREBRAL CORTEX AND THE AUTONOMIC NERVOUS SYSTEM. The lower levels of the autonomic system (e.g., hypothalamus) are undoubtedly under cortical influence. Lesions of the cortex (areas 6 and 4) in man are associated with vasomotor changes in the parts of the body affected by the cerebral injury. Similarly autonomic effects have been noted following ablations of these cortical areas in monkeys and chimpanzees. Shivering, sweating, pilomotor effects and gastrointestinal disturbances are also frequently associated with cortical lesions. The effect upon blood pressure and heart rate can be evoked by stimulating of area 6a and changes in respiration by stimulating area 6b.

Grasping movements and tonic innervation

The weakness on the opposite side of the body which occurs in lesions of the premotor area is not uncommonly associated with a group of phenomena to which various terms have been applied, e.g., "forced grasping and groping," "grasp reflex," "tonic innervation" and so forth. A description of these phenomena follows.

(1) Merely touching the skin between the finger

and thumb with a pencil results in slow flexion of the fingers. If the stimulating agent is withdrawn gently without disturbing the position of the patient's fingers no tightening of the grasp results but his hand and arm sometimes move through space (grobe) in the direction of the moving object, as if drawn by a magnet.

(2) When an object is placed in the paretic hand of the patient the fingers close slowly and gently around it, but any attempt made by the observer to withdraw the object often results in its being grasped more firmly. Nevertheless, when the patient clenches his empty fist he can relax the fingers again without difficulty.

(3) Any attempt to bend the arm or leg is met by an active resistance exerted by the antagonist (stretched) muscles; this differs from the resistance offered by the ordinary spastic limb in that there is no sudden giving way with a "clasp-knife effect."

Walshe and Robertson have made a critical study of these phenomena and find that they are separable into two distinct components: (a) the *grasp movement* and (b) *tonic innervation*.

The *gentle grasp* and the *groping movement* just described (see (1) above) are voluntary and not reflex acts. That is to say, though they are automatic in nature and are taken to indicate deterioration of the psychomotor functions, the patient can prevent their occurrences if asked to do so. They disappear in stupor or in coma. The gentle grasping movement follows tactile stimuli alone or visual and tactile stimuli acting together. The groping movements can be elicited by visual stimuli alone but not by tactile stimuli alone.

Tonic innervation (see (3) above) is a stretch reflex (p. 822). The *strong grasp* (2) which results when an attempt is made to remove an object from the hand is simply one phase—an incident—of this reflex. It is quite distinct from the gentle grasp movement. It results from the passive stretching of the flexor muscles of the fingers caused by the observer's attempt to extricate the object. It occurs in the unconscious patient.

Richter and Hines produced the "tonic grasp reflex" in adult monkeys by removal of the premotor area (fig. 377). Excision of the motor areas or the prefrontal areas from both hemispheres did not cause the effect. A similar reflex is present in normal infants, Robinson showing that in them it is sufficiently strong to suspend the body from a bar for 2 minutes. A grasping reflex has also been described for the foot in lesions of the premotor cortex; it occurs in the normal infant up to the end of the first year and is said to occur in 50 per cent

Mongolian idiots. It is elicited by stroking the sole.

THE PARIETAL LOBE

The somesthetic area

The *postcentral gyrus*, i.e., the band of cortex lying behind and including the posterior lip and

foot are recorded, below this are placed in order, sensory areas for the leg, thigh, trunk, shoulder, arm and hand. Cushing, for example, stimulated different parts of the area in a conscious patient; sensations on the contralateral half of the body were experienced, their locations bearing a constant relationship to the point stimulated. Dusser de Barenne discovered that the application of a

FIG. 377. Upper photograph; a young female baboon after bilateral extirpation of motor and premotor areas, showing grasping of left hand and spastic posture of other extremities. (From Fulton and Kennard.) Lower photograph; *left*, infant showing the suspended grasping reflex, *right*, infant showing resistance to removal of rod from the hand (from Chaney and McGraw).

All of the fissure of Rolando, is sensory in function. Excisions of the cortex from this region are followed by disturbances of cutaneous and somesthetic sensations on the opposite side of the body. As in the case of the motor area different levels of the postcentral gyrus are correlated with definite regions of the body (fig. 378). Thus, in the upper part of the gyrus, sensations from the

strychnine solution to the postcentral gyrus in monkeys caused sensory effects (paresthesias, hyperesthesia and hyperalgesia), most marked on the opposite side of the body but also on the same side. Deep sensibility is represented almost entirely contralaterally.

The sensory area of the cortex (*somesthetic area*) is not confined to the postcentral gyrus but em-

braces as well the *superior parietal lobule*, the *supramarginal gyrus* and the *angular gyrus*, and, for some type or types of sensation at least, e.g., proprioceptive, extends forward into the *pre-central gyrus*.

The method of strychninization for mapping the sensory representation in the cortex has its limitations, the diffuse action of the drug rendering strict localization impossible. Moreover, strychninization evokes maximum sensory responses, the finer differences in sensation being blurred or obscured. Marshall, Woolsey and Bard have used a method to map out the cortical representation of tactile sensibility in monkeys, based upon the fact that impulses set up by stimuli applied peripherally can be recorded as action currents from the surface of the hemisphere (fig. 000). They found tactile sensations represented contralaterally in the post-central gyrus (areas 3, 1 and 2). Bilateral repre-

texture, etc., and of the positions of our limbs in space. Through cortical activity a particular sensation is subjected to critical appraisal, compared with or related to another simultaneous or consecutive sensation; thereby, its intensity and nature are accurately judged. Thus, according to Head, the somesthetic area of the cortex, through the integration of the primary sensations, becomes endowed with three discriminative faculties. These are:

(a) **SPATIAL RECOGNITION**—the appreciation of spatial relationships in space, e.g., the recognition of position, passive movement of the limb, the discrimination of points, and the localization of a point which has been touched.

(b) **RECOGNITION OF THE RELATIVE INTENSITY**—different stimuli, e.g., that one object is warmer or colder than another, or that one stimulus is more painful than another.

FIG. 378. Action potentials recorded from postcentral gyrus during tactile stimulation of points on hand. (Part of figure from Marshall, Woolsey and Bard.)

sensation was not observed, except occasionally, for the face. In no instance was evidence obtained for the precentral representation of this sensation.

All somatic sensory impulses ascend in the medial fillet to the thalamus. This nuclear mass is the final destination of crude sensations (protopathic, see p. 803). The finer sensations of touch and temperature and the sense of position and movement are relayed to the cortex by fibers which ascend through the internal capsule and corona radiata. The function of the somesthetic cortex, according to the views of Head and his associates, is not, however, simply to record these several primary sensations. Its activity lies in the psychological sphere; cortical sensation, to quote these observers, is one of the "elementary processes of the mind." The somesthetic area brings its discriminative and synthesizing abilities to bear upon the primary sensations which it receives, and from these are formed our perceptions of the qualities of external objects, such as their size, shape, weight,

(c) **RECOGNITION OF SIMILARITY AND DIFFERENCE**—appreciation of the shape, relative size and texture of objects, and the estimation of their weights. These abilities are frequently grouped under the term *agnosis*.

In a lesion involving the somesthetic area or other, but usually all three, of these faculties are disturbed. Yet as a rule they are not all affected to the same degree. Spatial recognition shows the greatest disturbance the farther forward the lesion lies in the somesthetic area. Appreciation of intensity is disturbed most by lesions involving the foot of the postcentral gyrus and the supramarginal and angular gyri. Recognition of similarity and difference is affected most by lesions involving the middle of the postcentral gyrus.

In the lesion confined to the cortex, the impulses ascending from the thalamus and conveying the primary sensations, e.g., light touch, temperature, passive movement and position, etc., upon which the cortical faculties depend, are intact and

tions are appreciated. The subject of such a has difficulty, however, in bringing the vary discriminative ability to bear upon the tion in order to judge it, and he is unable to esize different sensations into a composite sion which will enable him readily to identify ject. When tested, he is uncertain in his rs, which tend to vary from moment to nt, and it is difficult for the examiner to nine the threshold for a given sensation. gh he recognizes that an object is warm, he t say whether it is warmer or less warm than er object which he has felt previously or at me time. Similarly, although he knows a limb has been moved, he cannot say into osition it has been placed. He responds to stimuli, but also with inconstancy, and he is even less consistent in his answers when the th of the stimulus is increased. He cannot the point touched and may respond when not d (hallucination of touch). The weights ects placed upon the hand cannot be esti-, and a fabric (e.g., silk or tweed), though be smooth or rough cannot be recognized. for example, a piece of tweed is placed in d the patient may say, "I feel it, it is rough, ave no idea what it is."

tonia may also be a symptom of lesions of sory cortex; it corresponds in distribution to as of the sense of position and passive ent.

cortex at the lower end of the somesthetic ongue and face area) appears from the of Bornstein to be the *center for taste*. ea lies adjacent to the motor cortex govern- e muscles of mastication. It has been ly taught, but on doubtful evidence, that ter for taste lay close to that for smell, , in the region of the hippocampal gyrus. ation of this sense in the parietal lobe by ein is based upon a study of war wounds of in.

SUBCORTICAL LESION of the sensory path- e., from the thalamus to cortex) disturb- n the cortical faculties obviously must since many of the impulses from which aculties are integrated will fail to reach stination. The defects, however are much they are in terms of the primary sensations, ccordance with the three cortical faculties. s not the uncertainty and inconstancy of e characteristic of lesions of the somesthetic The patient either feels a sensation or he t, and gives the same answer each time a

given stimulus is repeated. The loss of the indi- vidual sensations is often severe but when the particular stimulus is increased a response can usually be obtained.

Motor effects of a generalized type are produced by electrical stimulation of the posterior part of the superior parietal lobule (area 5, parietal ad- versive field). These are movements of the head and eyes to the opposite side. Stimulation of the angular gyrus causes conjugate deviation of the eyes to the opposite side.

Attacks of Jacksonian epilepsy, due to lesions of the sensory cortex, may be preceded by sensory aurac—comprising pricking sensations, "pins and needles," sensation of cold, etc.

THE TEMPORAL LOBE. THE CENTERS FOR SMELL AND TASTE

The primary cortical center for hearing is situ- ated in the transverse gyrus of Heschl lying in the floor of the lateral cerebral (Sylvian) fissure, and an adjoining small area of the superior temporal gyrus. Fibers from the medial geniculate body reach this *auditosensory* area via the posterior limb of the internal capsule; they constitute the *auditory radiation* (p. 1024). In the audito- sensory area the fundamental auditory sensations—intensity, quality and pitch—are appreciated. The area is bilaterally represented. A large part of the cortex of the superior temporal gyrus con- tiguous to this primary area is *auditopsychic* in function. Herein the analysis and interpretation of auditory sensations, and their integration into more complex perceptions take place. The audito- psychic area is mainly unilateral, being on the left side in right-handed individuals and vice versa.

Electrical stimulation of the posterior part of the superior temporal gyrus (area 22) in man causes adverse movements similar to those fol- lowing stimulation of area 6a β .

Fibers descend from the cortex of the temporal lobe to: (a) the *medial geniculate* body and *inferior colliculus*; the former is therefore connected with the auditory area by both ascending and descend- ing paths. (b) The *nuclei of the pons*. These fibers constitute the *temporopontine tract* which traverses the posterior limb of the internal capsule and the outer part of the base of the cerebral peduncle. Through these fibers and the ponto- cerebellar tract the temporal lobe is in communica- tion with the cerebellum. The temporal lobe is connected also with the thalamus by both ascend- ing and descending fibers.

The CENTER FOR SMELL is situated in the uncus and the anterior part of the hippocampal gyrus (pyriform area). Owing to the close relationship of these parts of the rhinencephalon to the temporal lobe, lesions of the latter (e.g., tumor, abscess, etc.) are not uncommonly associated with disturbances of the olfactory sense.

A LESION OF THE TEMPORAL LOBE may result in—

(a) *Aphasia*. In a series of left temporal lobe lesions reported by Frazier and Rowe this disorder was present in 36 per cent. Others have reported higher percentages (e.g., Kolodny, 57 per cent).

(b) *Auditory disorders*, deafness, tinnitus (ringing or buzzing, etc.) or auditory hallucinations (e.g., hearing voices) may occur.

(c) *Olfactory and gustatory disorders*, impairment or loss of smell, or olfactory hallucinations, the subject imagining he smells some disagreeable odor. Taste may be defective or there may be disagreeable gustatory sensations.

(d) *Dreamy states*. The subject experiences a sensation of unreality in which hazy memories of long past events are awakened. Such states are due to involvement of the region of the uncus and are sometimes on this account called uncinata attacks. In normal persons certain odors arouse a milder but somewhat similar sensation.

(e) *Disturbances of memory*.

(f) *Hemianopia* (pp. 1007, 1008).

(g) *Epileptiform seizures*. The convulsions may be ushered in by adverse movements (fig. 376) and are frequently preceded by an auditory, olfactory or gustatory hallucination (aura), or by the dreamy state. The fit is sometimes precipitated by a sudden noise.

THE OCCIPITAL LOBE

The gray matter forming the walls of, and surrounding the calcarine fissure (on the medial aspect of the occipital lobe) constitutes the primary cortical center for vision—the *visuosensory area*. From the broad stripe of Gennari which can be seen with the naked eye this area is commonly known as the *area striata* or, following the numerical terminology, as area 17. It has been considered in more detail on page 1009. Its histological features have already been touched upon (p. 886). The *visuopsychic area* wherein the visual sensations are interpreted and integrated into more complex perceptions is contiguous to the *area striata* lying on the lateral aspect of the occipital lobe (area 18).

Stimulation of the anterior part of the lateral surface of the occipital lobe causes conjugate deviation of the eyes to the opposite side (occipital field, area 19).

THE PHYSIOLOGY OF SPEECH AND SOME OF ITS DISORDERS

The first stage in the development of speech is the association of certain sounds—(words)—with visual, tactile and other sensations aroused by objects in the external world. These associations are “stored” as memories. After definite meanings have been attached to certain words, pathways between the auditory area of the cortex and the motor area for the muscles of articulation become established, and the child attempts to formulate and pronounce the words which he has heard. This act of verbal expression involves the coördinated movements of a large group of respiratory, laryngeal, lingual, pharyngeal and labial muscles. Later, as the child is taught to read, auditory speech is associated with the visual symbols of speech, and finally, through an association between these and the motor area for the hand, the child learns to express his auditory and visual impressions by the written word.

APHASIA

This term is applied to those disorders of speech resulting from defects in the nervous mechanism underlying the comprehension and use of symbols (words, numerals) for the formulation, transmission and reception of ideas. Aphasia is not simply a defect in the pronunciation of words as a result of the paralysis of the muscles of articulation. The innervation of the latter—motor area, corticobulbar fibers, cranial nuclei or peripheral nerves—is not necessarily affected. The defects in aphasia involve higher neural levels; they lie in the psychical sphere.

Before giving Head's views on aphasia, a short account of previous ideas on the subject may be helpful to the reader.

The views of the neurologists of the 19th century had the merit of simplicity. These observers, whom Head refers as the “diagram makers,” conceived of the language faculty as built up of several separate components. Each of these, supposedly, was represented by a definite anatomically circumscribed area of the cortex, and could be affected independently of the others.

Two of these centers were *sensory* and two *motor*. All four were linked together by association tracts.

such a scheme, memories of spoken words were stored in the superior temporal convolution—the ditopsychoic center; the cortex in the region of the angular gyrus was the repository of visual word memories. These two receptive areas comprised what was referred to as Wernicke's zone. The pair of motor centers, i.e., those presiding over the coordinated movements concerned in vocalization and writing were called respectively the glossokinesthetic and cheirokinesthetic centers. The former was located in the posterior part of the 3rd frontal convolution; the latter in the hind part of the 2nd frontal convolution, in most instances on the left side. Diagrams were drawn confidently to show these four centers with their interconnections, and the type of aphasia which would result from the destruction of one or other component part of the neural mechanism. Broca (1861) believed that *motor aphasia* (see below) was the result of a lesion of the glossokinesthetic area (Broca's area), especially of the left side. Defects of the ability to write—*agraphia*—were held to be the result of the involvement of the cheirokinesthetic center. *Sensory* aphasias were classed as *auditory*—loss of the comprehension of audible speech—and *visual*—the inability to understand written or printed words. The former was held to be due to injury of the second temporal gyrus; the latter to injury of the angular gyrus. The extreme proponents of this view even considered that every memory, auditory or visual, has its anatomical representation, so that a lesion limited to a small group of nerve cells would cause the loss of only those word memories for which they were regarded as centers.

The different types of aphasia which were recognized may be briefly described.

(a) **MOTOR APHASIA (Broca's).** This term was applied to the type of speech defect in which the patient is almost speechless, but there is no paralysis of the muscles of articulation. Though unable to express his thoughts in words, he can understand what is said to him and can read. He is usually able to utter a few words of an ejaculatory nature, "oh my," "dear me," "damn," etc. Sometimes he is able to say the last words which he spoke just before the onset of his illness, as the oft cited case of the librarian whose only words were, "lists complete."

(b) **AGRAPHIA.** This term indicated that the patient was unable to write though motor speech and the comprehension of written or spoken words were possible. The movements of the hand and other acts were not necessarily impaired.

(c) **AUDITORY APHASIA OR "WORD DEAFNESS"** were the names given to those defects of the language faculty in which the subject, though able to hear, does not understand spoken words. He is as a person listening to a strange language. The power of speech, writing and the comprehension of written or printed words are retained. He may be able to repeat words spoken to him, and instead of answering a question may simply repeat the questioner's words; this phenomenon is called *echolalia*.

(d) **VISUAL APHASIA OR "WORD BLINDNESS" (ALEXIA).** Vision may be unaffected yet the recognition of written words or numerals and the appreciation of their meanings are impaired or lost.

In 1906 these mechanical conceptions of the speech faculty and the production of aphasia were challenged by Pierre Marie. He claimed that there was only one true type of aphasia—sensory aphasia—due to a lesion in Wernicke's zone, and associated with a lowering of those intellectual capacities upon which were based the use of symbols in the expression of ideas. Thus, not only was the comprehension of written or spoken words defective but the ability to solve problems in arithmetic, and to perform certain other mental tasks were impaired. He maintained that the classical motor aphasia of Broca was simply *anarthria* (see below) due to involvement of the motor cortex governing the muscles of articulation plus sensory aphasia, and that a pure motor aphasia, i.e., a defect of speech due to the loss of "motor images" did not exist. Marie denied the existence of isolated cortical centers governing the different aspects of the speech faculty, and attacked the belief that aphasia was the result of the destruction of images—motor, auditory or visual—in such specific areas. He reexamined the brains of Broca's first two patients, which had been preserved in the Musée Dupuytren in Paris, and found no confirmation of the view of Broca that the posterior part of the third frontal convolution was necessarily involved in aphasia. In the first brain, the lesion was not confined to Broca's area but involved Wernicke's zone. The second specimen did not show a circumscribed lesion but, on the contrary, a generalized wasting; the posterior part of the third frontal convolution was not especially implicated.

The terms in the classification given above, e.g., motor aphasia, agraphia, "word deafness," etc., are still sometimes employed, but it is understood that they refer to the outstanding features of a

given case rather than that they denote clear-cut types.

Head's classification of the aphasias

Head's views, based upon an exhaustive study of patients suffering from gunshot wounds of the cortex, are also strongly opposed to the conception of the speech faculty being dependent upon circumscribed anatomical centers. He considers speech to be a highly integrated cortical process—a special aspect of intelligence—yet one which can suffer with little lowering of the general intellectual level. The different components of the speech faculty, he decides, cannot be separated from one another by disease. Nor, consequently, can the types of aphasia be classed as “motor” or “sensory,” but in any type deficiencies on both the receptive and the executive side can be demonstrated. Head concludes that aphasia is a state in which the power to use words and other symbols as instruments of thought and expression is affected or, as he expresses it, “aphasia is a defect in symbolic formulation and expression.” The more complicated or abstract the idea which must be understood or expressed, the greater is the difficulty. Thus an aphasic may be able to name *objects* correctly but fails to find the word for a more *abstract idea*, e.g., color. Shown a black object, for instance, and asked to name its color he fails to do so, yet indicates that he recognizes that it is black by saying “what you do for the dead.” An aphasic soldier when shown a red object said, “what the staff wear.”

Head, as a result of an extensive investigation of aphasic patients, devised a series of six tests of graded severity. These tests are briefly as follows:

(1) *Naming and recognition of common objects.* Six objects, e.g., a pencil, key, knife, etc. The patient is asked to name each object as it is pointed out to him. Next he is asked to point to each object as its name is called out. He is then given cards upon each of which the name of one of the objects is written. He is asked to indicate the object named.

(2) *Naming and recognition of colors.* This test is carried out in a manner similar to that described for test (1) except that eight strips of differently colored silk are substituted for the six objects.

(3) *Man, cat and dog test* is designed to investigate the powers of reading and writing in their most elementary forms. The printed words “man,” “cat” and “dog” are employed. The subject is asked to read these words; to write them from dictation; to copy them or to repeat them after hearing them spoken. Pictures of a man, a cat and a dog are also shown and the patient asked to write or to speak their names.

(4) *The clock tests.* The patient is requested to set the hands of a clock in the same positions as those of a similar one set by the observer. He is then told to set the clock from verbal or printed commands. Again he is asked to state the time aloud or by writing, of a clock set by the observer.

(5) *Coin bowl tests.* Pennies are placed one in front of each of four bowls. The patient is asked verbally and in writing to place a coin in one or other of the bowls according to their number in the row. He is then asked to give an order himself and to carry it out according to his own words.

(6) *The hand, eye and ear tests.* The patient is requested to repeat the movements of the observer which consist in touching an eye or an ear with one or other hand. When this is done correctly the patient's hand which moves is of course diagonally opposite to the hand of the observer. A much easier form of this test is the imitation of the observer's movement as reflected in a mirror. This simply requires matching without calculation.

The aphasic frequently fails to recognize that when the one hand is brought to his contralateral eye or ear the hand crosses the face. A further part of the test is to ask him to imitate the positions shown in pictures or form upon cards or to carry out the movements from printed and verbal instructions. Finally, he is asked to write down movements made by the observer.

From the results of such tests upon a large number of aphasics, Head divides speech defects into four groups. A brief account of these based upon his description, follows.

(1) **VERBAL DEFECTS.** The outstanding feature is if a defect in the utterance of individual words of all kinds. The power to express an idea in words is practically lost. The patient, however, is not entirely speechless but can usually utter a few monosyllables, “yes” or “no,” etc., or ejaculations and emotional expressions, such as, “damn,” “dear me.” When the disorder is less severe, the words are mispronounced but sentences are correctly constructed. For example, one patient said that he had trouble with “tenical terms” (technical terms) and that he “had *diffulty* in remembering what you do with a skull, *tri-tre-tripine*” (trepan). Another spoke of “*claration* of war by the *Ollie*” (declaration . . . Allies). Another would say “*pyramerad*” (pyramid), “*sissiors*” (scissors) and “*oboid*” (ovoid). Such patients read with difficulty and writing is very defective or impossible. They usually understand printed or oral commands. This form of aphasia resembles the classical motor aphasia described on page 89.

(2) **SYNTACTICAL DEFECTS** (agrammatism or jargon dysphasia). The patient is voluble but speaks a jargon in which, though the individual

words may be fairly accurately pronounced, they are strung into short phrases or badly constructed sentences without articles, prepositions or conjunctions. The ability to read aloud is impaired, and curiously enough such a patient, though he can write a well constructed letter, may be quite unable to read it coherently. Such a one when asked the contents of a letter which he had just written replied, "I cant; I know, I suppose in time, not now, funny thing, why." In other instances the words themselves are often slurred over, mutilated and may be unrecognizable. Speech sometimes resembles "baby talk." Thus one patient when asked what his right arm felt like replied "Tiff-ant from uffer um" (different from other arm). The understanding of ordinary conversation is defective.

(3) **NOMINAL (NAMING) DEFECTS.** In this type of speech disorder the patient has difficulty in finding the right word to express his meaning or in naming a well known object. Such patients will often employ a descriptive phrase in substitution for the word which they cannot recall. For example, a painter when asked to name a series of colors could not say "violet" but instead explained that "it was made with black, red and a bit of blue." Another when asked to tell the time from a clock which had both hands at 12 replied "That's when you eat." These patients can draw from a model either directly or from memory, after it has been shown and then removed, but are usually unable to draw from imagination. They write a coherent letter with difficulty, usually fail to carry out simple arithmetical exercises and confuse the values of coins.

(4) **SEMANTIC² DEFECTS.** A patient suffering from this type experiences little difficulty in articulating speech, can name objects, understands individual words and some sentences, but the general meaning of what he hears escapes him. He often fails to follow his own utterances to an intelligent conclusion, his sentences tailing off as though he had forgotten what he had started out to say. When shown a picture he picks out the details but fails to grasp the meaning which it conveys to others. Such a patient therefore misses the point of a joke whether this is printed, told to him, or is in pictorial form. He fails to comprehend the significance of much that he sees and hears. There is no impairment in the pronunciation of words, though speech tends to be in short jerky sentences, syntax and intonation are not disturbed.

²Semainein = to signify.

Head, though he discards the conception that the neural basis of speech consists of strictly localized anatomical "centers" wherein resides *exclusively* one or other of the speech functions—auditory, visual or motor—believes that regions exist in the cortex "where the progress of some mode of action can be reinforced, deviated or inhibited." These regions constitute foci of integration—convergence points for association paths. Destruction of one or other of such foci or "knots" of association paths will depress *as a whole* the psychological processes underlying speech. The speech faculty is disabled; certain faculties are lost, while others are retained. Yet he points out that it is not logical to conclude that the abilities which remain and those which have been abolished constitute essentially separate and distinct functions from which the normal processes of speech have been synthesized, or that they are represented in specific circumscribed areas. To make a rather crude comparison—a person who has injured his foot, knee or hip, adjusts his locomotor apparatus as best he can. He hops or limps, yet it can not be argued that the hopping or the limping motion which he employs is simply one of the component movements employed in the normal act of walking which the injury has left intact. Nevertheless, the form which the disability assumes is undoubtedly influenced by the site of the injury. The ambulatory abnormality, for example, which results from an injury to the foot is different from that resulting from injury to the knee or hip. So too the nature of the speech disability is influenced by the particular region of the cortex involved. Thus if the lesion is in the neighborhood of the lower part of the precentral and postcentral convolutions of the dominant hemisphere the speech defect tends to be of the *verbal* type. In injury to the temporal lobe the speech defect tends to be of the *syntactical* type. In a lesion in the region of the angular gyrus of the dominant hemisphere the patient has difficulty, particularly, in finding names for things (*nominal defect*); damage to the cortex in the region of the supramarginal gyrus results in a *semantic defect*.

ANARTHRIA OR DYSARTHRIA (LITERALLY NO ARTICULATION OR DIFFICULT ARTICULATION)

Anarthria or dysarthria is loss or difficulty of speech due to paresis, paralysis or ataxia of the muscles concerned in articulation. There is no impairment of the psychical aspects of speech, i.e., "internal speech" is unaffected; there is no difficulty in the comprehension

of spoken or written speech. Other functions, e.g., swallowing, which are dependent upon the same groups of muscles as those used in speech, are also frequently affected. The condition may result from a lesion in the internal capsule or corpus striatum, bulbar nuclei or peripheral fibers, or from disease of the muscles themselves. Since the muscular mechanism of speech is innervated from both sides of the brain unilateral lesions are not followed by permanent anarthria. A lesion of the cerebellum or of its connections may also cause disordered control of the muscles of articulation (p. 931).

APHONIA (WITHOUT VOICE)

In this condition the patient can whisper but he cannot speak aloud. The muscles of articulation, tongue, lips, etc., are unaffected. Aphonia is due to the loss of power in the adductors of the vocal cords and is seen in lesions of the laryngeal nerves, but most commonly as a result of laryngitis or of hysteria.

APRAXIA AND AGNOSIA

APRAXIA (UNABLE TO ACT)

This is the inability to perform purposeful movements at will either by command or in imitation, though the muscles concerned show no paralysis or ataxia, and the patient understands perfectly what is required of him. He may, for example, when asked to protrude his tongue, be unable to do so, yet a moment later may without thought lick his lips. The defect is evidently in the psychical sphere and not due to disease of the cells of the motor area or of the pyramidal fibers. It is thought to be due to the interruption of association tracts connecting the precentral gyrus with higher psychical regions of the cortex where impressions of the movements of muscles are received, synthesized and stored as kinesthetic memories. This higher ideational area probably lies in the region of the left supramarginal gyrus in right-handed persons. A lesion of this region may cause bilateral apraxia; one confined to the anterior part of the corpus callosum is likely to interrupt fibers passing from the left hemisphere to the right precentral convolution and so cause apraxia of the left side.

AGNOSIA (NOT KNOWING)

Agnosia is a defect in which familiar objects, persons and places fail to be recognized (*visual agnosia*) though sight is normal; or the meaning and significance of sounds are not appreciated (*auditory agnosia*) though hearing is unaffected. The subject of visual agnosia is unable to name an object, not that he is aphasic in the true sense, but simply because the object is quite strange to him. If he does not recognize a written word it is on account of his general imperception, and not a result of a specific defect in the language faculty. When shown an object and asked to use it he behaves quite differently from the apraxic patient who recog-

nizes it but is unable to perform the necessary movement. The agnostic executes the movement well but it is inappropriate. If given a toothbrush, for example he may attempt to light and smoke it, or if given a cigar may use it to brush his teeth. The patient suffering from auditory agnosia cannot appreciate music or carry out oral commands. If these are given in writing they may be well executed.

EPILEPSY

Epilepsy is a condition characterized by recurring attacks or "fits," which when exhibited in typical form, consist of abrupt loss of consciousness and generalized convulsions. Two stages of the attack or seizure are recognized. In the first or *tonic stage* the muscles contract tonically, the spasms often twisting the facial features and holding the head and limbs in distorted positions. The arms are most commonly flexed and the lower limbs rigidly extended. After a few seconds the tonic spasm gives place to jerking movements often violent, of the limbs, face and muscles of mastication. This is spoken of as the *clonic stage*. Either during this stage or in the tonic stage the tongue may be bitten. Before the onset of the convulsion a large proportion of epileptics receive a warning in the form of a sensation or hallucination, the character of which varies in individual cases. The warning sensation or *aura*, as it is most commonly called, may be auditory, e.g., voices, music, etc., visual, e.g., flashes of light, sparks, etc., olfactory, gustatory, cutaneous, visceral, or kinesthetic, i.e., a sensation of movement of some part of the body. The kinesthetic sensation may be accompanied by actual movement of the part. Turning of the head and trunk to one side and deviation of the eyes are commonly observed. The patient sometimes utters a cry or scream—the epileptic cry—just before consciousness is lost. Loss of consciousness, however, does not always occur. On the other hand, attacks of sudden loss of consciousness, usually of brief duration, may occur without convulsions; such minor seizures are referred to as *petit mal* to distinguish them from the major attack or *grand mal*. After the convulsion the subject remains for a time in a stupor and may, especially after milder attacks, perform automatic acts, of which he has no recollection after regaining consciousness. This *automatism* occurs also in attacks of *petit mal*. Most commonly it consists merely in resuming some act or other upon which the subject was engaged before the onset of the seizure. Sometimes a number of convulsive seizures occur in rapid succession, the patient fa-

ing to regain consciousness in the intervals between them. This very serious condition is called the *status epilepticus*.

PATHOGENESIS

(a) *Jacksonian epilepsy*

In this type the seizure is due directly to a gross lesion localized in some part of the cerebral cortex. For example, a tumor, a foreign body, a cerebral birth injury or a depressed fracture of the skull may, by stimulating the cortical tissue in its neighborhood, precipitate the epileptic fit. A seizure arising from a definite cause of this nature is spoken of as Jacksonian epilepsy after Hughlings Jackson, the English neurologist of the last century who first described it. The term *focal epilepsy* is also sometimes employed. The fit commences in the region of the body governed by the irritated area of the cortex, but soon spreads to involve other muscular masses. All of one side of the body or even the opposite side may ultimately become convulsed. In the "march" of the convulsion the order in which the different muscles are involved can frequently be seen to correspond to that of their cortical representation. When the lesion is in the frontal, parietal, temporal or occipital lobes, and involves the adversive fields (p. 889), the attack is commonly ushered in by movements of the head and trunk and deviation of the eyes to the opposite side.

(b) *Idiopathic epilepsy*

Epilepsy which cannot be explained by the presence of any gross organic lesion of the brain is called idiopathic. Though many theories have been advanced, the cause of this type of the disease remains obscure. There is a tendency today to look upon epilepsy as a symptom, or rather a group of symptoms common to several rather than as a single primary pathological state. Convulsions, whose features are indistinguishable from those of the epileptic seizure, occur in a number of conditions. In animals convulsions may be produced by injections of absinthe or caffeine. Hypocalcemia (p. 702), hypoglycemia (p. 584), cerebral edema or anemia and other states are accompanied by generalized convulsions of an epileptiform character.

With regard to the neural mechanism through which the fits are produced; some authorities believe that the convulsions are the result of *increased excitability of the cortex* and therefore comparable in their mode of production to those of

the Jacksonian type, or to those produced by experimental stimulation of the cortex. Others view the convulsions as a *release phenomenon* due to the inhibition of cortical areas which normally exert a controlling influence upon lower motor centers. According to Pollock and Davis convulsions of either the tonic or clonic type are not necessarily due to cortical discharge since they can be induced (by means of certain drugs, e.g., picrotoxin) in decerebrate animals.

Nor is there any general agreement as to the nature of the underlying factor or factors responsible for the seizures. A change in the acid base balance toward the alkaline side, a disturbance of the water balance, defective oxygenation of the arterial blood, instability of the vasomotor system resulting in spasm of the cerebral vessels, and abnormalities of endocrine function have all had their advocates. Others believe that the primary pathogenic factor lies within the cortical tissue itself—an inherited inferiority of nervous structure resulting in instability of the higher cerebral centers. The defect, according to this view, is psychological in nature—essentially one of personality. This is the so-called *psychogenic theory* of Clark. According to some, organic changes in the brain are responsible. Changes in the brains of epileptics have been observed at operation and post mortem; destruction of cells and sclerosis of the hippocampus—Ammon's horn—have been described by several observers. It is more likely, however, that the changes described are the result rather than the primary cause of the seizures. They are found usually in inmates of institutions, i.e., subjects of the severer forms of the disease.

A few words with regard to some of the other possible pathogenic factors: Geyelin was the first to connect *alkalosis* with epilepsy. He observed that during periods of starvation the epileptic attacks were reduced in frequency and less severe. He attributed the beneficial result to the ketosis which occurs during fasting. A ketogenic diet, that is, one high in fat content and low in carbohydrate, was later advocated by Wilder and by Peterman in the treatment of epileptics. A considerable degree of success has been reported from the employment of this treatment.

There is evidence that the *water balance* is disturbed in epilepsy. There are water retention and increased volume of the cerebro-spinal fluid and apparently an increase in intracranial pressure. Increase in the quantity of supracortical cerebro-spinal fluid (frontal and parietal areas) and of the fluid in the subarachnoid spaces generally, can be

demonstrated by encephalography in subjects of epilepsy. Since the days of Hippocrates the moist brains of epileptics have been remarked upon. Water intoxication (p. 19) is well known to produce convulsive seizures and the intravenous injection of a hypotonic solution into animals increases their susceptibility to the action of convulsant poisons. Hypertonic solutions, on the other hand, lower the intracranial pressure and reduce the convulsive tendency. Cerebral edema, from whatever cause, is likely to result in convulsions. Though it is not suggested that a disturbance of the water balance is the primary cause of the epileptic seizure, it is believed, nevertheless, as a result of these several observations that water retention and the resulting rise in intracranial pressure are predisposing factors. The dehydration treatment of epilepsy is based upon this belief. The patient is maintained upon a fluid intake restricted to from 8 oz. to 12 oz. daily, and foods of high water content curtailed. According to Fay, one of the chief proponents of this method of treatment, the good effects resulting from a ketogenic diet are due not so much to the ketosis produced but to the reduction in the water content of the body, since less water is retained upon a diet of protein and fat than upon one rich in carbohydrate.

It is generally conceded that *defective oxygenation* of the arterial blood predisposes to convulsive seizures, and Lennox found that in a large proportion of the epileptics whom he examined between attacks, the oxygen saturation of the arterial blood was below the normal value. He also found that a seizure was readily induced in epileptic subjects by reducing the oxygen of the inspired air to around 10 per cent. Anemia of the cortex is also well known to be conducive to the production of convulsive seizures. Convulsions may be induced in the monkey by tying the carotids, and Stewart and associates found that in cats convulsions frequently occurred during the restoration of the blood flow to the brain after a period of complete arrest of the intracranial circulation. Also, the convulsions which occur in subjects of heart block (p. 192), or accompanying the depressor reflex resulting from stimulation of a hypersensitive carotid sinus (p. 245) are attributed to a temporary anemia of the brain.

During the epileptic attack pronounced *vascular changes* occur in the cortex. These have been observed during operations by Foerster, Penfield and other neurological surgeons. According to

Foerster, constriction of the pial vessels and pallor of the cortex occur during the tonic stage, vascular dilatation leading to marked congestion of the surface of the brain during the clonic stage. Constriction of the retinal vessels may also be observed during the attack. It is perhaps tempting to assume that the vascular constriction, and the resulting anemia of the cortex, is the cause of the fits and that the primary defect is some abnormality of the vascular nerves. From the evidence, however, such a conclusion is not justified; the vascular constriction may simply be an associated phenomenon—another manifestation of the underlying pathological state. Penfield, from his observations of the exposed brains of a number of conscious epileptics, states that the one invariable vascular accompaniment of the epileptic seizure is constriction and cessation of visible pulsation of the pial arteries. Frequently the radial pulse also disappears. Pallor of the cortex—capillary constriction—though it was observed by Penfield upon some occasions during the attack, occurred more commonly after the attack was over. Though, occasionally, very definite improvement has resulted from removal of the cervical sympathetic, which furnishes constrictor fibers to the cerebral vessels, as a rule this operation is not followed by any appreciable benefit. Furthermore, experimental epilepsy can be readily induced in animals after cervical sympathectomy. These observations, however, do not necessarily exclude the possibility that spasm of the cerebral vessels plays a part in the epileptic attack, for removal of the sympathetic would not abolish the vascular reactions if, as Penfield believes, they may be brought about through local reflex arcs provided by nerve plexuses upon the intracranial vessels themselves.

A summary of the factors which may exert an influence upon epileptic seizures is given in table 80. The characteristics of the electro-encephalogram in epilepsy are described on page 906.

The study of convulsions produced experimentally in animals by various means, and of measures which raise the convulsive threshold (i.e., which reduce the susceptibility to convulsive seizures) has led to the discovery of a valuable drug for the treatment of the epileptic subject. In experiments on cats Merritt and Putnam found that the convulsive threshold to electrical stimulation of the cortex was raised most notably by *sodium diphenyl hydantoinate*, and have reported highly successful results from its clinical use.

HEADACHE

Headache is one of the commonest of symptoms, and occurs in a great variety of diseased states, e.g., arterial hypertension, chronic nephritis, gastrointestinal disease, etc., yet the mechanisms underlying its production are far from being clearly understood. It seems certain that the factors concerned are not the same in all instances. The headache occurring in such intracranial conditions as tumor, abscess or hemorrhage is usually the result of the general rise in intracranial pressure, but may also be due to the irritation of

TABLE 80

List of physiological changes in the brain which may influence seizures

(After Lennox and Cobb)

	CONDITIONS WHICH MAY TEND TO	
	Prevent seizures	Precipitate seizures
Oxygen	Rich supply	Poor supply
Acid-base equilibrium	Acidosis by means of fast-ing, fat diet	
	Ingestion of acids or acid-forming salts	Alkalosis by means of ingestion of alkali
	Breathing high CO ₂	Hyperpnea—"blowing off" CO ₂
Chemical constituents	Low chloride (?)	High chloride (?)
	High calcium (tetany)	Low calcium (tetany)
Water balance	Dehydration	Hypoglycemia Edema
Intracranial pressure	Decreased	Increased
Intracranial circulation	Impaired	Unimpaired

sensitive nerve endings in the immediate neighborhood of the lesion. As pointed out by Elsberg, sudden changes in intraventricular pressure, whether a rise or a fall, are likely to cause headache, quite apart from any significant change in general intracranial pressure. Severe headache lasting many hours frequently follows the withdrawal of cerebrospinal fluid by lumbar puncture. Elsberg considers that in these instances lowered pressure within the third ventricle, and upon the optic thalami, which form the ventricular walls, is the essential factor. For example, if a block exists in the ventricular system behind the third

ventricle, headache does not result from lumbar puncture. Headache also occurs during encephalography when the injected air enters the third and lateral ventricles. The site of the headache bears a relation to the location of the injected air, varying with different positions of the head.

Headache may result from neuralgia of the nerves of the scalp, from disease of the frontal sinuses, or from osteitis or periostitis of the cranium (syphilis, Paget's disease, etc.); or it may be a radiated pain from the extracranial branches of the trigeminal to its intracranial terminals. It may sometimes be due to pain (p. 860) referred from a thoracic or abdominal viscus to the superficial tissues of the head supplied by the trigeminal, which is related segmentally to the vagus. The temporary but severe pain felt in the frontal region by a normal person after quickly swallowing ice-cream is an example of a referred pain². It is not within the scope of this work to enter into a discussion of headache from the clinical viewpoint,³ but the possible factors concerned in the production of pain in the ordinary common headache and in migraine will be considered.

In healthy persons the most common causes of headache are eyestrain and constipation. The pain in the ordinary type of headache, and also in most other types is of intracranial origin. The sensitive regions are the vessels of the pia mater and their immediate surroundings, and the larger vessels of the dura mater. From observations upon conscious patients during intracranial operations it seems established that the cortical gray matter and the dura mater itself are insensitive. Fibers mediating pain are distributed in the intracranial branches of the trigeminal nerve. The latter, however, are not the only pathway for pain impulses from within the cranium for, according to Elsberg and Southerland, headache occurs after section of the sensory root of the trigeminal nerve on both sides; intracranial branches of the vagus probably contain pain fibers.

The sensitivity of the pial and dural vessels has led to the belief that the majority of headaches are of vascular origin, the pain being due to vasodilatation and the excitation of the sensitive nerve endings situated upon the vessel wall or in its immediate neighborhood. It is thought that vasoconstriction first occurs, followed by vasodilatation and congestion of the pia mater. The

³ For the more clinical aspects of the subject the reader is referred to an article by Spriggs (Lancet, 1935, 2, 1).

initial vasoconstriction and the resulting local anemia may also, it has been suggested, result in edema and a rise in intracranial pressure. The severe though brief headache which follows the intravenous injection of histamine—a potent vasodilator substance—can be cited in support of the vascular theory. In some persons who are subject to headaches, a headache with features identical with those from which the subject suffers is caused by the administration of histamine. In view of the discovery that the intracranial vessels are under nervous control, the production of headache through reflex action initiated from various parts of the body, and in excitement or emotional states, is readily understood upon the basis of a vascular mechanism. It is also reasonable to assume that certain toxic substances may, in some instances, induce headache through a direct action upon the vessels. The headache associated with constipation is, however, apparently of reflex rather than of toxic origin. It is often relieved very quickly by a movement of the bowels, a fact, as pointed out by Alvarez, which seems to preclude the possibility that it is the result of the absorption of toxins from the intestine (p. 509). In the headache accompanying visual defects, reflex vasomotor changes within the cranium and pain referred from the eye to the terminals of the trigeminal nerve, are probably the chief causative factors.

Not only the vessels of the meninges, but the intracerebral vessels and the choroid plexus as well, are supplied with nerve fibers, and the fact, as mentioned above, that headache follows the injection of air into the ventricles, indicates that the deeper parts of the brain are sensitive. It is possible, therefore, that vasomotor reactions involving the intracerebral vessels or variations in pressure within the ventricular system may be factors in the production of ordinary headache.

MIGRAINE. (Synonyms, megrim; hemicrania; sick headache.) This is a type of headache whose special features entitle it to be placed in a class by itself. The headache is periodic, severe and often accompanied by nausea and vomiting. In many instances some type of sensory disturbance (aura) ushers in the attack. This frequently takes the form of scintillating colored lights or the so-called fortification figures, that is, zig-zag luminous bands which are suggestive of the walls of a turret. The visual hallucinations have a homonymous distribution, that is, they occur in the right or the left halves of the visual fields (p. 1006). Temporary hemianopia may follow, or blindness of the

central part of the retina may accompany the visual sensations, which are then toward the periphery of the field of vision. Cutaneous, auditory or gustatory auras occasionally occur. The headache is localized at first but soon spreads to involve the entire half of the head; the pain is then on the side opposite to that of the hallucinations. Not unusually, however, the headache is bilateral, or is unilateral to start with, and later spreads to involve the opposite side of the head.

The mechanism underlying the production of migraine is a matter for speculation. The premonitory sensory phenomena quite clearly point to a cortical disturbance and strongly suggest that the condition has a vascular basis. According to Bramwell, the aura is associated with spasm of the pial vessels, the headache with vasodilatation, and, possibly, with localized edema. The pallor of the face which frequently accompanies the attack, and the constriction of the retinal and temporal vessels, also support the conception that migraine is of vascular origin. Migraine in some instances appears to be a form of allergy, like asthma (p. 366) and hay fever. It is conceivable, as Spriggs suggests, that an antigen of some sort (possibly taken in the food) combines with antibodies in the endothelial cells of the vessel walls and causes the liberation of histamine with consequent vasodilatation and localized edema—that is, an “intracranial urticaria.” This would result in pressure upon the sensitive nerve endings in the pia mater.

Several other theories have been advanced in attempts to explain the pain of migraine, e.g. increased pressure within the ventricular system due to temporary blockage of the foramen of Monro, or to hypersecretion by the choroid plexus. There is no evidence, however, that temporary changes of this character ever take place. Pool and his associates did not find the cerebrospinal fluid pressure greater in patients during the migrainous attack than in a group of normal controls. Timme subscribes to the theory that the headache, in certain instances at any rate, is due to swelling of the pituitary body within an abnormally small pituitary recess. This mechanical conception has not, however, received support from other observers who have been unable to demonstrate by roentgenography that the pituitary recess is significantly smaller in subjects of migraine than in those who have never suffered from an attack. Others hold the view that a low blood sugar is, in some cases, at least, an important factor, citing in support of their belief the headache of fasting and of hyper-

nsulinism, and the relief which follows the administration of glucose or of adrenaline.

There is some evidence that hypersecretion of the gonadotropic hormone (or hormones) of the pituitary may be a factor in the onset of the migrainous attack. Riley, Brickner and Kurzrok have reported that in twenty out of a series of twenty-nine female subjects of migraine the gonadotropic principle appeared in the urine preceding the attack. At the same time the female sex hormone (oestrin) was either absent from the urine or present in very reduced amounts. Of the two male subjects studied, one showed a similar relationship between the appearance of the pituitary principle in the urine and the onset of the attack; in the other subject an excretion of the pituitary principle occurred prior to four out of eight of his attacks. In support of the view that a disturbance in the gonad-hypophyseal mechanism plays an important rôle in the production of migraine these authors call attention to the following observations. The first attack of migraine frequently coincides with puberty; attacks commonly occur before menstruation, when the excretion of estrin is reduced and the gonadotropic principle may appear in the urine; the subject is usually free from attacks during pregnancy when the excretion of the estrogenic hormone is increased, whereas the gonadotropic (follicle-stimulating) principle of the pituitary is reduced; relief from the condition commonly follows the conclusion of the menopause, and in the case of men the attacks cease or become infrequent after the fifth or sixth decade.

Among the many agents which have been employed in the treatment of migraine are the following; sedatives such as *bromides*, *peptone* or *foreign protein injections*, *ergotamine tartrate* and the *estrone*. The latter, it will be recalled, depresses the gonadotropic activity of the pituitary, a fact which in the light of the views held by Riley and his associates, may explain the benefit which has been reported to follow its use. Estrone is especially effective in the treatment of headache associated with the menstrual period. The mode of action of ergotamine in relieving the headache is not clearly understood. Pool did not observe any consistent effect of the drug upon the pial or cerebral vessels. The dural vessels, however, are constricted by ergotamine; if, as some claim, the pain of migraine originates in the dural arteries the constrictor effect of the drug upon these vessels may explain the relief which follows its use. Ergotamine causes a rise in systemic blood pressure, an

increase in cerebral blood flow and a rise in cerebrospinal fluid pressure, effects which in no way explain its beneficial action.

The electro-encephalogram

In 1929 Berger discovered that changes in electrical potential could be recorded from the head of the human subject by means of pad electrodes applied to the scalp or needle electrodes placed in contact with the periosteum of the skull. In normal subjects three wave frequencies may be recorded—the *alpha*, *beta* and *delta* rhythms.⁴ The alpha rhythm consists of rhythmical oscillations in electrical potential occurring at the rate of 10 per second (fig. 379). The waves have a voltage of about 50 microvolts on the average. The alpha waves appear with the eyes shut but are abolished by visual activity or by mental effort (e.g., mental arithmetic); they return again as soon as the men-

FIG. 379. Normal alpha rhythm, upper, *shut* and *open* refer to eyes (after Lemere); center electro-encephalograms during an attack of petit mal (after Gibbs and associates); lower, during a grand mal seizure.

tal work ceases. Adrian and Mathews found that the waves are present when the eyes are open, provided that the visual field is uniform (i.e., free from pattern). Any attempt of the subject to fix the eyes upon any detail results in the disappearance of the waves. A visual field which flickers causes the potential waves to assume a rhythm of the same rate as the flicker. Adrian and Mathews conclude that the waves are due to a spontaneous beat of an area of the occipital cortex concerned with pattern vision; when the cells of this area are not engaged in visual activities they tend spontaneously to discharge impulses at a fixed rate. The beta rhythm is faster than the alpha (25–50 per second) and of lower voltage (5–10 microvolts) and is obtained best over the precentral (motor) region of the cortex. The delta waves have a frequency of from 1 to 5 per second and a voltage of from 20 to 200 microvolts; they can be recorded very rarely

⁴ A faster rhythm (*gamma*) appears in rare instances.

from a normal adult while awake, but appear normally during sleep or during the waking hours in early childhood. Generally speaking, their presence in an adult, except during sleep, indicates some pathological process in the brain—tumor, epilepsy, raised intracranial pressure, mental deficiency or depression of consciousness by toxic or other factors. When present they tend to displace the alpha rhythm. Neither the beta nor the delta waves are abolished by closing the eyes. The electrical potentials just described are of cortical origin; the record of such changes might therefore be appropriately termed cortical electrograms. According to Kornmüller, records from different cortical areas show characteristic differences in wave pattern which change rather abruptly as the boundary between two areas of dissimilar histological structure is crossed.

Abnormalities of the electro-encephalogram in brain tumor, especially of so-called silent areas of the brain, and in epilepsy, promise to be of definite diagnostic value. In cerebral tumor or brain abscess, as shown by Walter and by Case, the functionally depressed brain tissue surrounding the lesion gives out waves of slow rhythm (delta waves) which, combined with a loss or diminution in the alpha rhythm over the occipital region may be of considerable aid in localization.

Epileptic seizures are characterized by pronounced departures from the normal rhythm. In *petit mal* attacks, large slow waves appear about a second before the attack is clinically manifest, and displace the previous rhythm. Each large wave is followed by a sharp spike deflection (fig. 379). Early in a *grand mal* seizure, waves of relatively high frequency (10–30 per sec.) and of low voltage appear, but as the attack progresses these fast waves give place to slower and larger waves which continue into the stage of stupor following the seizure. Delta waves may be a prominent feature of the electro-encephalogram of epileptics between seizures.

In normal sleep the pattern of the electrical potentials recorded from the brain varies with the depth of unconsciousness. During light sleep, delta waves make their appearance while the alpha waves superimposed upon the slower rhythm of the latter persist. In deep sleep the alpha rhythm disappears being replaced by delta waves, or in some instances by a faster rhythm with a frequency of about 14 per second. During the light sleep before awakening the record shows only an odd slow wave. As consciousness returns the tracing consists of an intermittent alpha rhythm which becomes continuous upon waking.

CHAPTER LXX

CONDITIONED REFLEXES. SLEEP

Definitions

The ordinary reflex with which we are all familiar is an inherited characteristic of the species and is not dependent upon previous experience. Its pathways are established at birth. This type Pavlov terms an *inborn* or *unconditioned reflex*. For example, food placed in the mouth of a newborn puppy evokes a secretion of saliva. The reaction depends solely upon the stimulation of receptors (taste, touch, etc.) in the mouth. When, on the other hand, the young animal sees or smells a piece of meat for the *first* time no secretion of saliva results. Yet if an animal who has eaten meat on previous occasions sees or smells a morsel, profuse secretion of saliva occurs. This reaction, which depends upon previous experience, Pavlov has termed a *conditioned* or *acquired reflex*. Its pathways are not fully established at birth but are developed by training. Quite evidently the reaction of the older animal is the result of an association established in the past between the stimulus applied to the receptors of the mouth, and the appearance or smell of the food, i.e., a visual or olfactory stimulus. The former is called the *unconditioned*, the latter the *conditioned stimulus*. Not only the qualities of the food itself but changes in the environment extraneous to the food, if they occur in association with feeding, can serve as conditioned stimuli.

Conditioned reflexes may be either of an excitatory character, e.g., the secretion of saliva, or have an inhibitory action. The former are termed *positive* or *excitatory*, the latter *negative* or *inhibitory*.

POSITIVE OR EXCITATORY CONDITIONED REFLEXES

In the great majority of the experiments performed by Pavlov and his school the secretion of saliva was chosen as the indicator of the conditioned response. In order to follow the secretory reaction with precision the opening of the parotid submaxillary duct is transplanted to the cheek and chin, respectively. The saliva is collected by means of a special apparatus consisting of a funnel placed over the duct opening and leading into a system of tubes. The secretion is measured in drops by means of an electrical recorder. The animal is held in a stand by means of straps and

occupies a sound-proof chamber separate from that of the experimenter (fig. 380).

The reflex is established in the following way. While the animal is being fed (unconditioned stimulus) a stimulus, e.g., a flash of light, which is quite alien to the food itself (conditioned stimulus) is applied. After this association of the two stimuli has been repeated a number of times, the flash of light alone (i.e., food is withheld) evokes a secretion of saliva. This is called a *conditioned alimentary reflex*. Motor reactions, e.g., movements of the lips and jaws, snapping, whining or barking, and movements of the limbs, accompany the salivary secretion and constitute an integral part of the reflex. The number of repetitions of the experimental procedure, or "lessons," necessary to establish the reflex varies in different animals and in experiments of different types. Many types of conditioned stimulus (visual, auditory, olfactory and cutaneous) have been employed by Pavlov and his associates.¹ In establishing the reflex the conditioned stimulus must precede the unconditioned stimulus and, except in the case of secondary and trace reflexes, to be presently described, must overlap it for at least a brief period. If the conditioned stimulus *follows* the actual feeding it is quite ineffective, i.e., it will not evoke a reflex when subsequently applied alone. After the period of training, in order to demonstrate the conditioned response satisfactorily, the animal should be alert, not drowsy, and preferably hungry; furthermore it should not be distracted by some extraneous stimulus, e.g., a strange sound or light, which sets up unconditioned motor reflexes.

Other types of positive conditioned reflexes

CONDITIONED DEFENCE REFLEXES. Acid injected into an animal's mouth (unconditioned stimulus) causes a profuse secretion of saliva which washes the offending material away. A condi-

¹ Among these are the following,—the sound of a metronome, horn, bell, buzzer, tuning fork, organ pipe or of bubbling water; variously shaped objects, lights, figures or rotating discs; thermal, tactile and painful cutaneous stimuli; the odor of such chemicals as amyl acetate or vanillin. The cessation of a previously continuous stimulus, e.g., a buzzer; the rapid change in the intensity of a stimulus, or even the change in the rate of a rhythmical sound, e.g., a beating metronome, may serve as a conditioned stimulus (see also p. 911).

tioned reflex to acid is readily established by a series of trials in which a conditioned stimulus, e.g., a light, and the unconditioned stimulus (acid) are applied in combination. Or if an animal has been given a colored acid, the animal salivates when shown water of the same color. Also, if a painful stimulus is applied to the animal's paw (unconditioned stimulus) during some form of conditioned stimulation (e.g., sound of a buzzer) the motor reactions (e.g., drawing up the limb, turning the head towards the injured part, etc.) which follow the application of the combined stimuli occur, after a few trials, when the conditioned stimulus is employed alone. The painful stimulus may serve also as a conditioned stimulus for a salivary reflex; then, unless the painful stimulus is intense the usual defence reactions are suppressed, salivation alone

the mere sight of the syringe, or the approach of the attendant who had previously administered the drug; the injection of an inert fluid is particularly effective.

SECONDARY AND TERTIARY CONDITIONED REFLEXES. A second stimulus may be conditioned by linking it up with a conditioned stimulus already firmly established. A defence conditioned reflex, let it be supposed, has been established with an electric shock to the front paw as the unconditioned stimulus and a touch upon the hind paw as the conditioned stimulus. A second neutral stimulus (e.g., the sound of bubbling water) is now applied and withdrawn a few seconds before the application of the primary conditioned stimulus (touching the hind paw) but the unconditioned stimulus (electric shock) is omitted. If the two stimuli are associ-

FIG. 380. Illustrating arrangements for experiments upon conditioned reflexes (from Pavlov, *Lectures on Conditioned Reflexes*, International Publishing Company, New York).

resulting when the stimulus is applied. The alimentary reflex is in this case stronger than the defence reflex. Pavlov points out that the subordination of the defence reaction by the alimentary reflex is seen when dogs are struggling among themselves for food. Minor injuries (e.g. of the skin) may then be sustained, but they do not evoke a reaction of defence; this is suppressed by the dominant food reflex. On the other hand, if the stimulus (such as one applied to bone) signals a more severe type of injury, or threatens the life of the animal, the defence reaction becomes prepotent.

Of great practical interest is the reflex which becomes established to the repeated injection of morphine. In the dog, morphine administration causes vomiting and salivation, followed by sleep. After a series of injections, these effects result from

ated in this way a number of times it is found that the second stimulus (sound of bubbling water) has itself acquired conditioned properties; when applied alone the defence reaction occurs. If a third stimulus (e.g., the sound of a tuning fork) is applied a short time before the second, but the primary conditioned and the unconditioned stimuli are omitted, it now, when employed alone, causes the conditioned response. It has not been found possible to establish a conditioned reflex of the fourth order, and conditioned reflexes beyond the second order cannot be established for alimentary conditioned reflexes.

TRACE CONDITIONED REFLEXES. In establishing this reflex the unconditioned stimulus is made to follow the conditioned stimulus after an interval when the reflex has been established the con-

conditioned response follows the conditioned stimulus after an interval of the same duration. For example, a tactile stimulus is applied to the skin for half a minute and then withdrawn; one minute later acid is injected into the mouth. After a number of repetitions it is found that when the tactile stimulus is applied alone, although no secretion occurs during its application, a response follows after a minute's interval. Also, if an animal is fed at regular intervals, say every 30 minutes, it is found that after a series of such feedings secretion occurs spontaneously, thereafter, at intervals of approximately 30 minutes, though no food is given. In these instances the time interval itself has evidently acquired the properties of a conditioned stimulus.

THE BIOLOGICAL SIGNIFICANCE OF CONDITIONED RESPONSES

Conditioned reflexes enter very largely into animal and human behavior. Many such reflexes are developed naturally as the experiences of everyday life become enriched, and associations accumulate. Stimuli arising in the environment are constantly calling forth conditioned responses of various types serving as signals to guide the animal in its choice of action. By training and discipline more complicated reflexes can be established, such as those forming the basis for the tricks of performing animals. In such instances the sound of a word (command) or a movement made by the trainer serves as a conditioned stimulus to some motor action of the animal. In the training and education of the child conditioned reflexes also play a prominent rôle. Animals with more highly developed nervous systems are capable of the more complicated reflexes, and though one can scarcely speak of certain conditioned reflexes, such as the secretion of saliva following the flash of a light or the sound of a tuning fork, as an intelligent act, the ability of an animal to develop conditioned responses is, nevertheless, a measure of its intelligence. Conditioned reflexes also play an important rôle in the psychology of sex and, according to Pavlov, in the induction of sleep (p. 918). Conditioned reflexes, which are established under the ordinary circumstances of life are termed *natural*. Those which are established experimentally or by special methods of training are called *artificial*. There is, however, no essential difference between the two.

INHIBITION OF CONDITIONED REFLEXES

Inhibition as applied to conditioned reflexes is divided by Pavlov into *external* or *indirect* and *internal* or *direct*.

A. EXTERNAL INHIBITION. The conditioned reflex is inhibited by some form of stimulation quite apart from the conditioned stimulus itself. The inhibition arises in a part of the brain other than that in which the conditioned reflex is initiated. For instance, some disturbing factor, a sudden noise, a strange smell, a light, a fresh object in the room, or the entrance of a stranger tends to abolish a conditioned reflex, which in quiet surroundings can be readily elicited. The extraneous stimulus arouses the animal's curiosity and distracts its attention or, in Pavlov's words, evokes an *investigatory reflex*. This purely unconditioned reflex consists of what its name implies—pricking of the ears and turning the eye and head toward the source of the distraction. If the extraneous stimulus is repeated often enough its inhibitory effect is weakened or abolished; the conditioned responses of an animal placed in strange surroundings are at first inhibited but return later. A painful stimulus also sets up an *unconditioned defence reflex*—barking, struggling and other motor reactions which exert an inhibitory effect upon the conditioned response.

B. INTERNAL INHIBITION. This will be considered under the following headings: (1) *extinction of the conditioned reflex*, (2) *conditioned inhibition*, (3) *inhibition of delay*, and (4) *differential inhibition*.

(1) *Extinction of the conditioned reflex*. If a conditioned reflex is repeated a number of times and the unconditioned stimulus (e.g., feeding in the case of an alimentary reflex) always omitted, the response becomes weaker with each repetition, its latent period lengthens progressively and the reflex finally disappears. The reflex is said to have undergone *extinction*. If, however, after every few repetitions of the reflex the conditioned stimulus is followed by the unconditioned stimulus, extinction does not occur. The former stimulus is then said to have been *reinforced* by the latter. For example, if a conditioned alimentary reflex has been established to the sound of a buzzer, the application of the latter alone calls forth at first a prompt and ample secretion of saliva. After a variable number of repetitions in which the conditioned stimulus is not followed by feeding, i.e., not reinforced, the secretion becomes less each time and finally ceases. After an hour or two the reflex recovers spontaneously. Extinction is due to inhibition of the cortical elements of the reflex. That it is not due simply to fatigue of the salivary gland or of the nervous centers is shown by the fact that after complete extinction, reinforcement of the conditioned stimu-

lus causes the reestablishment of the reflex. Moreover, the reflex continues at full strength after a great number of repetitions if it is followed every few times by reinforcement.

After a reflex has undergone extinction, some external stimulus may temporarily remove the inhibition. That is, just as an extraneous stimulus can inhibit the excitatory phase of a conditioned reflex, so also can it inhibit the inhibitory state. This is called *dis-inhibition* or the "*inhibition of inhibition*."

(2) *Conditioned inhibition*. If, after a positive conditioned reflex has been firmly established another stimulus is combined with the conditioned stimulus for a number of trials but reinforcement is always omitted, then, though the conditioned stimulus still causes the customary response when applied alone (and regularly reinforced), it is quite ineffective when in combination with the extra stimulus. For example, an alimentary conditioned stimulus is established to the beat of a metronome. Later, a buzzer is sounded with the metronome, but the combination is not followed by feeding. After a series of such trials the metronome causes a secretion, but the combined stimuli, metronome plus buzzer, are without effect. The sound of the buzzer is termed a *conditioned inhibitor*, and the inhibitory effect which it produces, a *negative* or *inhibitory conditioned reflex*. Usually, in order to demonstrate the inhibitory effect, the primary conditioned stimulus and the conditioned inhibitor must overlap. (It does not matter which commences first.) If one ends a second or two before the other commences, the inhibitory effect does not develop. Moreover, if the pause between the first and second stimulus is 10 seconds or so, the latter then causes a positive conditioned reflex of the second order (p. 908).

(3) *Inhibition of delay*. If during the establishment of a conditioned alimentary reflex, the conditioned stimulus is continued for only a brief period, 1 to 5 seconds, before the unconditioned stimulus is applied, then the conditioned response (secretion of saliva) follows almost immediately upon the commencement of the conditioned stimulus. That is, the reflex has a very short latent period. If after such a *simultaneous reflex* has been established, it is repeated day after day, but the conditioned stimulus is continued a little longer each time before the reflex is reinforced, the latent period becomes lengthened in proportion to the interval between the application of the two stimuli. The almost simultaneous reflex has been converted into a *delayed reflex*. In other words, postpone-

ment of reinforcement has caused the conditioned response to be inhibited during the first part of the action of the conditioned stimulus; during the latter part of the action of the conditioned stimulus the secretion of saliva commences and increases in amount up to the moment when reinforcement ordinarily would have occurred.

(4) *Differential inhibition*. This will be described in the next section.

The examples of internal inhibition just given show the high degree of discriminative and adaptive powers of which the cerebral cortex is capable. Though such adjustments are purely automatic they are effected with great delicacy and an apparent purpose. In the case of extinction, for instance the futility of secreting saliva for food which does not follow appears to have been "recognized." The purpose in conditioned inhibition is quite as evident as in positive conditioned reflexes and the inhibition of delay is clearly an adjustment which economically times the secretory response to the moment when food is "expected."

It is not only in these special instances that internal inhibition occurs, for all positive conditioned reflexes, though reinforced regularly, undergo inhibition if repeated over a period varying in different animals from weeks to months or even years. They become progressively weaker, the latent period lengthens out and they ultimately disappear. The tendency of conditioned reflexes to undergo inhibition is an inherent property. Reflexes in which the conditioned stimulus is of long duration, i.e. delayed reflexes, are more prone to disappear than those in which the unconditioned stimulus follows the commencement of the conditioned stimulus by a brief interval, i.e., simultaneous reflexes.

ANALYZING AND SYNTHESIZING FUNCTIONS OF THE CEREBRAL CORTEX

Of the numberless agencies in the environment to which the organism is exposed the great majority might be termed neutral in that they exert neither a beneficial nor an injurious effect. The actions of others are either of definite physiological value or detrimental to the animal's existence. Through the analyzing mechanism possessed by the nervous system the stimuli to which the latter types of agent give rise are given conditioned properties. Such stimuli are picked out to serve as signals for reactions on the part of the animal appropriate to the respective agents (beneficial or noxious); they are therefore of the utmost biological importance. The cerebral cortex also possesses synthesizing

mechanisms whereby individual stimuli are fused into conditioned complexes (p. 912).

The analyzers

Pavlov divides the neural mechanism of the organism upon which the discriminative faculties depend into a number of *nervous analyzers*. These are constituted of the nerves of special sense, and the afferent nerves of the joints and skeletal muscles, together with their respective receptors and central connections. Thus he speaks of *visual, auditory, olfactory, gustatory, cutaneous* and *motor analyzers*. The receptor of each class is especially responsive to its own type of stimulus—light, sound, etc. The central part of each analyzer, i.e., its terminations in the cerebral cortex, is capable of a very fine discrimination between the different intensities and qualities of stimuli within its own class. The visual analyzer, for example, discriminates between the intensity and quality of different visual stimuli, the auditory analyzer between the intensity, pitch and quality of sounds, the motor analyzer between the various messages (proprioceptive) received from the muscles and joints—and so on for the other analyzers.

In the past, the study of these analyzers, i.e., of the sense organs, has been based very largely upon subjective data gleaned from experiments upon the human subject. The discovery of conditioned reflexes, however, has provided a reliable method for the study of the analyzing functions which being purely objective can in consequence be employed in animal experimentation; the conditioned salivary secretion, for example, is a reaction which readily lends itself to precise measurement and timing.

Generalization and differentiation

If a conditioned reflex is established, say to the sound of a tuning fork of 800 cycles per second (c.p.s.), it is found that tones somewhat higher or lower in the scale have also acquired conditioned properties. Also, after a conditioned reflex has been established to a tactile stimulus applied to a certain definite skin area, the stimulation of neighboring areas is also effective. The response, however, becomes weaker the farther away from the original area that the stimulus is applied. This *generalization of stimuli*, as Pavlov calls the phenomenon, is seen also in the case of olfactory, visual and other analyzers. If, however, the original definite stimulus, for example the tone of 800 c.p.s., is always followed by reinforcement while other tones having a higher or lower frequency are em-

ployed without reinforcement, then only the tone of 800 c.p.s. evokes a response. The allied stimuli are said to have undergone *differentiation* from the primary stimulus. Pavlov ascribes the phenomenon to a form of internal inhibition—*differential inhibition*. He believes that originally the excitatory process in the cortical part of the analyzer is widespread, but through the antagonism offered by the internal inhibition set up by non-reinforcement of the allied stimuli, it becomes localized to only a minute cortical area corresponding to the receptors affected by the primary stimulus.

The degree to which differentiation between various types of stimulus can be developed is a measure of the analyzing ability of the cerebral hemispheres and is often amazing. The following examples are taken from Pavlov's monograph.

1. AUDITORY STIMULI

(a) *Differentiation of pitch*

Primary stimulus 800 c.p.s.

Differentiated stimulus 812 c.p.s.

(b) *Differentiation of rhythm*

Primary stimulus 120 beats per minute of a metronome

Differentiated stimulus 118 beats per minute of a metronome (Andreyev).

(c) *Differentiation of intensity.* The difference in the intensity of two sounds was so slight that it was detectable by the human ear only when one stimulus was followed immediately by the other. Differentiation was perfectly effected by the dog when the two stimuli were separated by an interval of 17 hours.

(d) *Differentiation of timbre and direction of sounds* was also demonstrated but the exact limits of differentiation were not determined.

2. VISUAL STIMULI

(a) *Differentiation of direction of movement or of the position of an object*

Primary stimulus. Clockwise rotation of a disc.

Differentiated stimulus. Anticlockwise rotation of the disc.

(b) *Differentiation of figures and shapes.* Some of the figures which were differentiated are shown in figure 381. A luminous circle thrown upon a screen was readily differentiated from a series of ellipses of the same luminosity; the series started with one having its axes in the ratio of 1:2; of the remainder each successive one approached a little nearer to the circular shape. Differentiation just failed when the ratio of the axes was 8:9.

(c) *Differentiation of luminosity.* Two shades of gray which to the human eye appeared

exactly the same, even when viewed simultaneously, were perfectly differentiated by the dog when an interval of a minute separated the primary from the differentiated stimulus.

- (d) *Differentiation of colors* failed in all but one animal investigated, and even it gave a doubtful result. Color vision in the dog is therefore either absent or very rudimentary.

3. **DIFFERENTIATION OF CUTANEOUS AND PROPRIOCEPTIVE STIMULI.** Differentiation was obtained for various types of tactile stimuli, e.g., contact with rough or smooth surfaces, pressure with blunt points arranged in different patterns, scratching with a small

FIG. 381. Examples of different figures which were successfully differentiated in experiments upon a dog. The letter T, shown in the upper left-hand corner of the figure, served for the positive stimulus; the other black figures and the white letter T were differentiated from the positive stimulus. In another dog the white cross was the positive stimulus from which the other white figures were differentiated (from Pavlov, *Conditioned Reflexes*, Oxford University Press).

brush in different directions. Differentiation was also demonstrated between stimuli applied to different areas, for variations in temperature, and between various passive movements, e.g., flexion of ankle as against extension.

4. **DIFFERENTIATION OF OLFACTORY AND GUSTATORY STIMULI.** Corresponding differentiations were established for various odors (e.g., vanillin, amyl acetate, camphor, etc.) and for taste sensations e.g., meat powders, sugar, cheese, etc.

Conditioned vasomotor responses have been established in human subjects, the unconditioned response (vasoconstriction of the opposite hand) being induced by immersion of one hand in ice-cold water. Ringing of a bell, a light pattern or a word spoken aloud by the

experimenter and whispered by the subject were used as conditioned stimuli.
